In conclusion I wish to call attention to the curious hallucinations of my second patient. Some writers, basing their position upon anatomical data, deny the existence of unilaterality of hallucinations (Soury and others), while on the other hand its existence is admitted by many psychiatrists. But the tendency to explain all sorts of hallucinations by means of certain specific cortical localizations is in my judgment of the same order as the desire to find a relation between hysterical and organic anesthesias. Our anatomical and physiological knowledge of the cerebrum is as yet too incomplete to authorize us to explain properly even those psychic phenomena that are dependent upon certain cortical centers. Mental operations are exceedingly complex and any special center of the sensorium by itself is not at all sufficient for their realization. Unilaterality of hallucinations, despite its apparent contradiction, with our anatomical conception of certain centers of the brain, exists nevertheless and, like many other mental phenomena, is not in a strict relationship with special cortical areas, but it depends upon multiple conditions. It should, therefore, have a place in mental semeiology.

MOOT POINTS IN THE TREATMENT OF FRACTURES.[1] [2]

BY MARTIN W. WARE, M. D.,

OF NEW YORK;

ATTENDING SURGEON GOOD SAMARITAN DISPENSARY; SURGEON TO THE CRIPPLED GUILD, SOCIETY FOR ETHICAL CULTURE; ADJUNCT SURGEON MT. SINAI HOSPITAL.

It is somewhat presumptuous on my part, in the face of so many existing treatises, to offer you anything of striking novelty in dealing with fractures, but I hope to impress upon you such features in their consideration as I have gained from nine years' experience at the dispensary, in teaching and from private practice. These deductions are based on three thousand cases.

First and foremost is the question of diagnosis of the fracture. It is all too common to see the medical attendant who suspects a fracture immediately try to elicit crepitus. Now the error here is, in not trying to determine the point of maximum tenderness by the gentlest palpation. For to this level, if at all, the efforts necessary to elicit false motion and the crepitus incident to it should be limited, and, therefore, I would emphasize the dignity that should be accorded localized tenderness, for it is often the only conspicuous symptom pointing to fracture. There is also a transmitted point of tenderness, *i.e.*, if the bone in its continuity be subjected to pressure, the pain is referred to a remote point which will be found to correspond to that of localized bone tenderness. Still another useful method of determining localized bone tenderness may be spoken of as bipolar bone tenderness, which is elicited by pressing together the two articular extremities of the bones, whereupon the patient will also refer the pain to the level of the fracture.

Up to this stage it is apparent that it is possible, without an anesthetic and without torture, to determine the existence of a fracture. Where deformity exists, and fracture is self-evident, it may eventually be necessary to use an anesthetic, to correct it, so the patient can again be spared the painfulness of crepitus. Until this moment arrives, from a humane standpoint, crepitus is in our estimation to be *subordinated* as a foremost sign of fracture; its greatest value is but relative to aid in differentiating fracture from dislocation, and it should then be elicited only under anesthesia. But as anesthesia carries with it a certain danger to life, the advent of the X-ray was heralded with great delight as a more humane method. This it has certainly proved to be, and where fracture has to be differentiated from dis-

[1] Read before the Harlem Medical Association of the City of New York, Feb. 5, 1904.

[2] Received for publication March 7, 1904.

location, it should unhesitatingly be employed in preference to anesthesia. In a general way, we would limit the use of anesthetics to the fractures of joints and of badly displaced and greatly impacted fragments.

In very young infants, no anesthetic need be employed. A quick, sharp movement will suffice to restore the alignment of the bone. The use of X-rays is not at all satisfactory in fractures of the joints of young children, since the epiphysis is so largely made up of cartilage, that the shadow does not form.

Fractures in the length of the shaft of adults do not urgently call for the X-ray as a means of diagnosis.

We must admit then that the simplest clinical methods, as of old, are ever at our disposal to recognize fractures in general. As the diagnosis of fractures and their replacement occupy so short a time, we advocate the use of ethyl chloride for this purpose, if any anesthetic be called for. Children who are terrorized by the X-ray can often be better examined under anesthesia and X-rayed at the same moment, if necessary. So much for the general principles covering the use of X-rays.

When called upon to treat a fracture, we often find ourselves in a quandary what to do first. At the best, be it said, nothing, until the right device can be applied. Barring this extreme injunction, we should suggest the application of a rubber or any bandage with moderate pressure to reduce the swelling.

In general, there is a tendency to the overtreatment of fractures. Our aim should ever be toward gaining a quick restoration of function, even if at times the alignment and cosmetic be not as perfect. This view I have begun to hold mainly in regard to joint fractures. Too much credit and not enough blame is placed upon the use of various devices in their treatment. The lower extremity left out of consideration for statical reasons, a callus at the expiration of two weeks is firm enough to keep the fractured ends of the bone in place, so that infant, youth or adult should, in most instances, be without splints at the expiration of this time, and the simplest of active, not passive, motions should then be allowed.

Prognosis.—The outcome of a fracture should be viewed from a medicolegal point of view, and we would then shape our prognosis in more exacting terms as to permanent and partial disability and length of time required for complete cure. Experience has taught us to be guarded, even in the most favorable cases. Instances may be multiplied of the occurrence of fat embolism, with sudden death, as occurred to the writer, in a case of fracture of the tibia one week after removal of the cast, or a musculospiral palsy incident to a perfectly healed fracture of the shaft of the humerus, and so on.

Apparatus.—The use of any ready-made splints, except in fractures of the thigh, should be deprecated. The best stock in trade are the simplest materials, plaster-of-Paris, pasteboard, cigar-box wood and non-absorbent cotton.

We want to dwell at some length upon the much maligned plaster-of-Paris. It is in such disfavor because the plaster bandages at our disposal, retailed in the shops, are improperly made and unfit for use. It is unfortunate that it is mainly in institutions that their use is best understood. Such plaster-of-Paris bandages as are sold in the shops may be made fit for use by unrolling, getting rid of the excess of plaster and rerolling them more loosely. The amount of pressure used in applying a roller bandage holds good for plaster bandages, a snug-fitting stocking, flannel or muslin bandage should be applied beneath.

In very stout and aged people, the use of plaster-of-Paris roller bandages is not advised, nor in infants on the upper extremity. Here we would rather use the molded plaster-of-Paris splint. Those who dread the ill consequences of a roller plaster-of-Paris bandage may split one its entire length just after its application and, if necessary, such a bandage may be so removed as to be fit for use again. To this end, all fancy devices are to be discarded and a mitre saw used which makes a straight line and ceases to cut upon reaching the muslin. The latter can then be cut with shears, the cast reapplied and held together with adhesive straps. Save such instances of spiral or oblique fracture with constant tendency toward displacement, we might wholly dispense with apparatus, for perfect adaptation is the best means toward perfect union.

We now pass on to the consideration of some special fractures. Until a few years ago, it was held that a fracture of the metatarsal bones rarely, if ever, occurred as a consequence of indirect violence. The army surgeons of all European nations had encountered a peculiar affection of the foot of the soldier on the march, known as foot-swelling (Fussgeschwulst), pied forcée. This received the most fanciful interpretations until the advent of the X-ray solved the mystery. The clinical picture is as follows: Either in the act of prolonged or forced walking or after imparting a sharp thrust to the fore part of the foot, a smart pain is experienced in the metatarsus. The individual persists in walking and a swelling appears over one of the metatarsal bones, usually the fourth. This is due to the callus which grows larger from day to day as the foot is used. With rest alone, the swelling subsides, but the application of a plaster-of-Paris bandage greatly facilitates matters. Such instances are encountered in civil practice.

Bennet's fracture is another but little known fracture. It is encountered as a fissure of the metacarpal bone of the thumb, caused by indirect violence. It is overlooked because of the absence of any callus or deformity, but characterized by a line of tenderness, extending along the entire length of the first metacarpal bone.

In the treatment of elbow-joint fractures, the

schools are as much as ever divided. To ascertain the exact direction of the line of fracture, and which bones are involved, are matters of great difficulty. Notwithstanding the existence of the X-ray, it is not possible to learn more precisely the particulars of this variety of fracture. Most of these occur during the period of adolescence and as the epiphyses are not ossified before the age of eighteen years, the cartilage is not pictured in the shadow of the X-ray. The question, therefore, remains: What can be clinically diagnosticated in fractures of the elbow-joint to enable intelligent treatment? Barring fractures of the olecranon, which are easily recognized, fractures of the neck of the radius and, finally, fractures of either condyle, all else as to line of fracture of the lower end of the humerus and the position of displaced fragment is largely speculative, whether or not the X-ray be used in one or more planes, or an anesthetic be given. It is held that such fragments can be replaced while the patient is under narcosis. This is frequently a physical impossibility, for the fractured ends of the lower part of the humerus are, in the first place, too small to grasp in the presence of the large amount of blood, nor can their position be influenced by any leverage exerted in motions of the forearm. It is necessary, as in other fluctuations, to rely on surface markings, such as hematomata, abrasions and ecchymosis which indicate the point of impact. Thus we learn to know the direction of force which determines the particular kind of fracture. Kocher has shown that these may thus be differentiated with ease clinically.

If the patient falls on the hand, the pronated radius transmits the force to the external condyles and fractures it. Again, if he falls on the olecranon, with the arm abducted, a like result follows. On the contrary, a fall on the elbow, with the arm abducted, fractures the internal condyle. In fractures of the internal condyle, extension and flexion are not as free as in fractures of the external condyle. Since the olecranon is mainly concerned in these motions, extension is possible to a greater degree than in external condyle fractures; and, again, the distance of the olecranon from the external condyle is greater than the internal.

The diagnosis thus reasonably determined, what shall be our attitude in the treatment of this fracture? There are those who make a hard and fast rule in treating this affection to vary the position at stated fixed intervals, hoping thereby to avert anchylosis and lessen the callus formation. Others, again, adhere to a fixed line of treatment, expecting thereby to better the position and healing chances of the fracture. We have tried both methods and have had failures. We think that in the long run what is to be aimed at in the treatment of elbow fractures is their restoration to useful function. The forearm, at right angles, or nearly so, is such a position. The fragments will heal as quickly in the flexed as in the extended position, and ultimately flexion is made.

It is our practice, if much deformity exists, to anesthetize the patient in order to remedy this condition; if no deformity exists, the forearm is left in its natural position at the time of fracture and, if possible, is brought near to a right angle without causing great force, and retained in a right angle pasteboard splint, where it remains for two or three weeks. At the expiration of this time, all callus having fixed the fragments, the forearm is placed in a sling and the patient allowed to move it of his own accord. The weight of the forearm often carries it into the extended position; the sling can then be again adjusted to a higher level, so as to bring the elbow into more marked flexion. Thus, gradually, by the fourth to the sixth week, the patient can voluntarily use the elbow over a wider area, and then, aided by massage and gymnastic exercises, further results are accomplished.

Similar to the sling, we have found the Thomas' halter of great service in children. The method of Jones' acute flexion is also simple and very effective. But, after all, the main point we wish to impress is that, with the lapse of time, the larger number of patients, young adults mainly implied, get a most useful arm, limited but few degrees in flexion or extension. A very small percentage, notwithstanding all treatment, have a permanent deformity, spoken of as cubitus varus. To offset this result, it was Allis' idea to treat the arm in extension to preserve the carrying angle, but in any case flexion must eventually be employed.

Kocher, Lane and a small following favor primary resection of the offending external condyle, and offer assurance of no interference with the growth of the arm. It has been claimed that these elbow fractures are mostly epiphyseal separations and that, therefore, the growth is likely to be interfered with. In answer to this be it said, that the line of fracture is juxtaepiphyseal and lies in the diaphysis and not the apophysis, wherefor no interference with the growth need be feared.

In Colles' fracture it is now universally agreed that a perfect reduction is the *sine qua non* for its healing. Here the X-ray has taught us that this fracture is no entity, as was originally held by Colles. A common clinical error is the notion that Colles' fracture and silver-forked deformity are synonymous. We have encountered the silver-forked deformity only exceptionally. An accurate diagnosis can be made by noting the differences in the level of the styloids of the radius and ulna. Normally, that of the radius lies at a lower level than the styloid of the ulna, but in fracture of the radius these styloids approach a level. This is known as the sign of Lanier and is used in skiagraphic work to determine old fractures. Next to this, local tenderness at some point over the lower third of the radius is most significant of fracture. The greater number of

Colles' fractures do not call for an anesthetic in their reduction. Only those attended with marked displacement, and they are fewest in number, require anesthetics. Once reduced, there is no tendency to redisplacement. For the location of fragments is caused by the violence and is not supplemented by muscular action. We have in 90 per cent. of cases treated these fractures by

Fig. 1.

Suspension treatment of Colles fracture.

suspension. It is a method spoken of by Malgaigne, brought to the fore by Moore, of Rochester, warmly endorsed in Heidelberg, and spoken of last year by Bier, as the ideal method. We have tried it in hundreds of cases and report the following advantages: great comfort, permitting the use of massage to the muscles of the forearm and earlier restoration of wrist motion, with less chances of anchylosis.

Where there is an effusion into the wrist joint, we also strap the wrist. Very deformed cases, even though they be reduced, do better under Rose's posterior splint. All devices in any way immobilizing the wrist joint are to be deprecated, since they favor anchylosis.

Fractures of the humerus, if low down, require some kind of extension device, as Bardenheur's method of vertical suspension, in addition to the plaster-of-Paris. The weight of the shoulder should be used for counter-extension, in order to guard aginst overriding of the fragments, which is apt to follow from the pressure of the plaster-of-Paris bandage, if the elbow be included in the dressing.

In fractures high up, the upper fragment has a tendency to be abducted, so the lower must be made to follow, by the insertion of a wedge pillow in the axilla, and the whole arm should then be bandaged to the chest with a snugly fitting plaster-of-Paris bandage investing the shoulder, or a splint, which answers the same purposes, made out of cardboard or plaster-of-Paris.

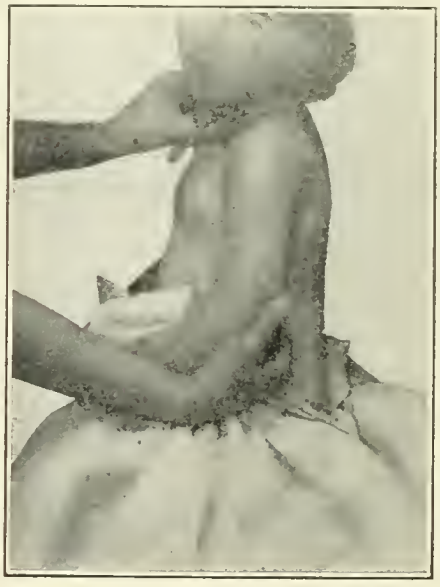
I want to call attention to the difficulty of diagnosticating fracture of the tuberosities, yet this is possible if we study just what motions of rotation, outward and inward, or abduction and adduction, are impaired.

In fractures of the clavicle we have despaired of obtaining anything other than a union with a small callus. A particular point to which we want to direct attention is a method to facilitate recognizing the fracture. By placing one hand upon the clavicle and elevating the arm in the perpendicular plane, by pressing on the elbow, the fragments move and crepitus is appreciated in the gentlest fashion.

A simple Velpeau bandage is what we have finally come to in treating clavicle fractures. Sayres' is efficient, but requires great care in its adjustment and gives no better results.

Fractures of the hand most commonly en-

Fig. 2.



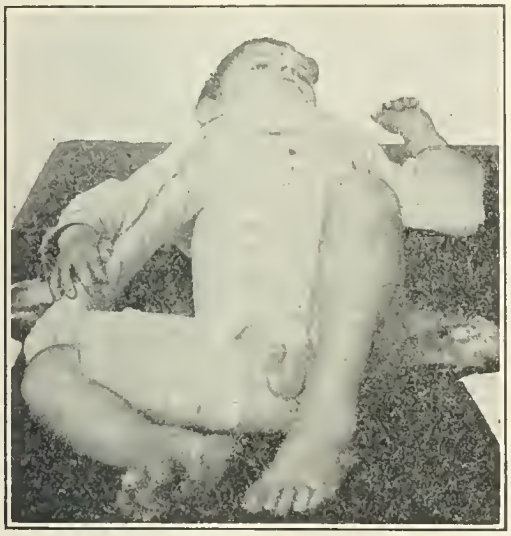
Illustrating the method of eliciting crepitus in fracture of the clavicle.

countered are those of the metacarpal bone. We wish to recommend the simple method of using a roller bandage, grasped by the hand, as an efficient splint. The extensor tendons are thus put on the stretch and act as a posterior splint, holding down the fragments which are, as a rule, slightly displaced, owing to the apposition of other bones, which also accounts for the fact that many days often elapse after the injury is inflicted before this fracture is recognized. Furthermore, it escapes detection because the

level of the line of fracture is near the articulation, and such motion as exists is interpreted as joint motion, but this mistake may be avoided by first locating the line of bone tenderness.

Fractures of the Femur.—I shall dwell mainly on those encountered in children. Here we have to contend with the undesirable feature that obliges these children to be on their back. If they are under three years of age, in the first stages of walking, a heavy plaster cast is unsuitable for ambulatory purposes and the use of a cast in the recumbent posture is a sorry thing at the best. For these instances, vertical suspension is an admirable method and one or both legs may be suspended, depending on whether the counter-extension of one buttock or both suffice to straighten the femur. This method of Hamilton or Shede is without doubt effective, though not pleasing to the eye. The toilet of the child can

Fig. 3.



The pasteboard triangle for the ambulatory treatment of fractures of the femur.

be most readily attended. However, it has been a matter of discussion that in hospital practice and in cases discharged from the hospital who come to us in the dispensary, a vulvovaginitis is found. To obviate the necessity of keeping these infants on their back and overcoming the sanitary obstacles, we present to you this very effective little known, method, first brought to the attention of the profession by the late Dr. Van Arsdale, whose untimely death left its development to posterity.

By the aid of a pasteboard triangle, the fracture of the femur is treated in an abducted and flexed position; positions that both favor a good apposition of the fragments, and also permit of the proper toilet. All the while the infant can be carried in arms. The results of this method are highly pleasing and patients need not be taken to the hospital encountering the disadvantageous change of diet at so tender an age, and the hospital, in turn, economizes in bed space. This method is applicable mainly to children under three years of age, though I have applied it up to the age of five, and it also suggests itself as an emergency measure until some definite plan is devised. For fractures in older children, not too high in the shaft, an ambulatory plaster splint is sufficient.

Your attention is now invited to the consideration of a form of fracture which was unheard of up to a few years ago. Finer study of the etiology

Fig. 4.

A case of coxa vara following fracture of the femur.

of the coxa vara brought to light the fact that untreated fractures of the femur were responsible for them. Such children fall like adults, striking the outer aspect of the femur. It has not been definitely decided whether an infraction of the neck, or epiphyseal separation is the consequence.

The history of these cases is as follows: After a fall the child complains of pain in the hip, there may or may not be outward visible signs of fulness in Scarpa's triangle or back of the trochanter, but the motions are impaired.

Under these circumstances, a synovitis is diagnosticated and the proper treatment instituted,

yet at the expiration of a very brief time, say two weeks, the child feels well and is allowed to walk. The gait is quite naturally halting at first; afterward, it is freer again, only to be followed at a later day by a limp. There are now external evidences of deformity. Elevation and prominence of the great trochanter, shortening and adduction. These are the consequences of allowing the child to walk about on a soft callus, as a result of which, the femur at the site of fracture bends under the weight of the body.

Since attention was first directed toward them these instances are fast being multiplied. Their treatment should be preventive, i.e., on suspicion of fracture. Rest in the horizontal position for four weeks with slight extension and abduction should be made imperative.

Fractures of the skull in children I deem worthy of special mention. They differ from those of adults, in that symptoms of cerebral compression are less pronounced and appear later. We are thus very apt to be misled as to the severity of the injury.

In infants under three years of age, the line of fracture follows the lines of ossification which

Fig. 5.

Showing extensive fracture of infant's skull without symptoms.

develops radically, and mistaking them for sutures, therefore, is very possible. The following history demonstrates the above remarks only too well: An infant survived her extensive fracture fourteen days, during which time she was discharged from two hospitals with merely a diagnosis of large hematoma. At the autopsy extensive fissuring of the skull was found. Just shortly before death, ocular symptoms were manifest, otherwise there were no paralytic symptoms of the limb, and the sensorium was close to that of a normal child until the last forty-eight hours, when she became comatose. About this time, I aspirated the hematoma. The microscopical examination of the fluid revealed brain cells. I would, therefore, in doubtful instances, recommend such a procedure to facilitate diagnosis before operation.

Fractures of the spine are perhaps the class par excellence, which would seem to call for operative treatment as soon as shock has passed off. But, unfortunately, most of the damage to the cord and spine are done simultaneously by the same offending force.

The justification and indication for this operation are prompted by the humane reasons that we have a fair analogy in the treatment of fracture of the skull, and the additional ground that in spite of X-ray localization, lumbar puncture and cytodiagnosis with cryoscopy, we can make no accurate differential diagnosis, between laceration of the cord, or compression by the fragments, leaving out of consideration that in nearly every instance there is a hemorrhage into the substance of the cord. Fracture of the lamina are most favorable for operation, and the use of X-rays is of decided value in these instances.

Fracture of the Patella.—We are opposed to an inflexible rule of primary operation of the patella, for within three or four days, under elastic compression and massage, the effusion into the joint may be sufficiently reduced to permit the fragments to be brought into contact, and when this is possible this treatment may be further encouraged and the patient allowed to walk about with a plaster cast within two or three weeks. The muscles should be massaged each day while the patella fragments are fixed by an assistant. Operation is indicated in multiple fractures of the patella and where the above treatment is not immediately responsive. The sprain most commonly encountered is that of the ankle-joint, and we wish to enter a protest against the meaningless term "sprain," whose pathology *non est*. In our experience with increasing practice over 90 per cent. of these sprains of the ankle are fractures of either one or both malleoli. Crepitus is difficult to elicit, in the face of the effusion, but marked local tenderness over the tip of each malleolus can always be made out and indicates the exact lesion. A great number of these cases, those with slight effusion, can be effectively treated with adhesive strapping. The more marked ones demand plaster-of-Paris bandages, including the whole leg.

In this connection we want to emphasize that the ambulatory splint has come to stay and is the form of a plaster device. It is useful in Pott's fractures, simple fractures of the tibia, and fractures of the femur in individuals of not too great a weight. Its success depends upon its proper application.

Such a plaster bandage should be so applied as to extend from the heads of the metatarsal bones to the condyles of the tibia. The turns of the bandage should be made extra heavy, just above the ankle-joint, and directly below the condyles of the tibia, the whole weight being carried by the column of plaster.

All of our Pott's fractures are allowed about after several days, at the outside a week, and the confinement to bed for long periods is a thing of the past.

Germany and Medical Practice.—The Institute of German Physicians issues a warning to young men against taking up the study of medicine, there being at present a glut of young doctors.

MEDICAL PROGRESS.

SURGERY.

Pyemic Glanders in the Human Subject.—A case which is of interest from its fortunate termination and the extreme rarity of laboratory glanders, is reported by J. C. Stewart (*Annals of Surgery*, July, 1904). The patient was a young woman physician, of twenty-seven years, who had been working with material taken from two very virulent and fatal cases of glanders in men who had become infected from diseased horses. Both died on the seventeenth day with multiple abscesses of the skin and in extreme sepsis. The incubation period was six days, the doctor having made the autopsy on an inoculated guinea-pig while she had an open wound of the finger. There was an absence of the usual skin lesions and the purulent foci were limited to the voluntary muscles. The points aimed at in the surgical treatment of the case after an exact diagnosis had been made were, (1) delay in the hope that the foci might become encapsulated by inflammatory changes in the surrounding tissues, and that the patient might become, as far as possible, immune by the manufacture of her own mallein; (2) the avoidance of local implantation of the *Bacilli mallei* upon wound surfaces where foci were eradicated. Among the methods for the prevention of further inoculation, the application of 95 per cent. carbolic acid and alcohol was more effective than the actual cautery, and the wounds healed quite promptly. After the wounds were closed there were repeated attacks of high fever, pain and prostration, but the patient finally made a complete though tardy recovery.

Sarcoma of the Clavicle.—M. M. Krinkoff's patient (*Roussky Vrach*, No. 21, 1904) was a girl of twelve years, who noticed a year ago a swelling on the right clavicle the size of a hazelnut. This continued to grow quite rapidly, reaching the size of a hen's egg. The tumor is round, painful, and quite dense. The skin over it is markedly distended, immovable, of a bluish red color, and pervaded by a net of blood vessels. The highest point of the swelling shows a beginning ulceration. The dimensions of the tumor from right to left (from its border at the left costo-clavicular articulation to the thickened end of the clavicle) are 28 cm., from above downward 32 cm., its circumference at the base 55 cm. The mobility of the joint is unimpaired; no œdema or pain in the right arm, neck, head or back. Operation under chloroform. Incision over the posterior surface of the tumor. The great amount of blood lost necessitated the injection of a physiological solution as well as the hypodermatic injections of camphor, while the large area of the resulting wound precluded the possibility of its closure, and it was protected by an aseptic bandage. The removed tumor weighed, together with the clavicle, 1,600 grms., and was shown microscopically to be a round-celled sarcoma. The course of convalescence was rather uneventful and the patient left the hospital fully recovered some six weeks after the operation. Unfortunately the further history of the case cannot be given by the author.

Tumors of the Chiasma and an Operation for their Exposure.—A case of this kind was reported by O. Kiliani (*Annals of Surgery*, July, 1904) in a boy in whom operation was decided on but was not carried out, as a sudden change in the boy's condition necessitated an operation for the relief of pressure in the lateral ventricles into which a cystic tumor had evidently perforated. The patient died a few hours later. Autopsy showed a cystic tumor, ruptured, in the region of the optic chiasma. The author worked out an operation on the cadaver which he suggests might be applied in such a case. A Wagner flap in the shape of an omega is made with the frontal bone, the base of which lies about half an inch behind the coronary suture. The dimensions of this flap are five inches in the median line, seven inches for the width, and the base where it is broken off, 3½ inches. The skin incision severs the temporal artery on both sides. The opening in the skull is made with the electric fraise, and then the flap is completed with the saw. After breaking the flap, the dura is incised and the longitudinal sinus tied. The frontal lobes may then be lifted with a spoon and the optic nerves exposed. Care must be taken not to tear the olfactory lobe.

Intravesical Separation of the Urine.—The necessity of obtaining the absolutely uncontaminated urine from the two kidneys and of obtaining all of it for a given time, has long been recognized. Catherization of the ureters afforded a ready means of obtaining this urine, but the method proved to be dangerous because of the probability of its being followed by ascending infection from the bladder. This would not be the case were it a fact that the bladders in patients requiring such investigation to be made were sterile, but such is rarely the case, and the tip of the catheter is almost certain to carry beyond the uretervesical valve sufficient contamination to render ascending pyelitis, if not a certainty, a sufficiently grave possibility to contraindicate catheterization. B. G. A. Moynihan (*Brit. Med. Jour.*, July 2, 1904) states that in his hands the segregator of Harris has not proved to be strictly reliable. This, as is well known, depends for its efficiency upon the principle of unfolding a tent-like structure in the rectum and expanding this beneath the trigone until two separate lakes with a ureteral opening at the center of each are formed in the floor of the bladder. Moynihan states that the first perfectly efficient instrument was created after some modification of the original pattern by Luys, of the Hôpital Lariboisière in Paris. It consists of three portions, a central one within which lies a chain attached at the handle of the instrument to a wheel. This portion, like the lateral parts, is straight to within about two inches of the end, where there is a marked curve forming almost a half circle. This portion is covered with a thin rubber sheathing. When the screw which works the chain is turned, the chain is tightened, and instead of lying in the hollow of the curve of the instrument, it is raised up, forming a diameter instead of a part of the circumference of the circle. The rubber sheathing is also raised up, and in this way a septum is formed. The lateral pieces fitting on to the sides of the central piece consist of two catheters having several eyes. Each catheter drains its own side of the bladder after the septum has been created. The Cathelin instrument is almost identical with this. When the instrument is passed, which is usually accomplished without the slightest difficulty, and it is felt to be within the bladder, it is withdrawn until the beak is in close contact with the back of the pubes. The septum is then liberated, and the water with which the bladder has been filled, is drawn away. Of Cathelin's instruments a variety of sizes are now made, so that with one or the other a fit of any size bladder can be made. Moynihan has found that Luys' instrument is difficult to pass in the male. He therefore considers it indicated in the female and Cathelin's for the male. He closes by stating that he considers the method an invaluable one and believes it to mark a great advance in our ability to differentiate renal conditions.

Animal Cage for Laboratory Use.—It is interesting to note that New York is following the example set

by Harvard and Johns Hopkins, in providing a means of carrying on surgical experimental work. DONALD GORDON, JR., and J. W. DRAPER MAURY (*Annals of Surgery*, June, 1904), present the working plans and a photograph of the cage which they have built for the Surgical Laboratory of Columbia University. The plans are drawn according to scale and are intended to be of practical service for those wishing to construct a similar cage. Any intelligent carpenter, in the opinion of the designers, can, by following these plans, construct a precisely similar cage. The characteristic of the cage is that it has an automatic self-flushing attachment similar to that in general use in public toilets. The odor, which is known to be extremely offensive in the case of all animals, but particularly of dogs, is in this manner kept largely in abeyance, and the animals themselves are reported to be much healthier than in the ordinary type of cage.

Diagnosis and Treatment of Perforating Typhoid Ulcer.—Any additional data and observations on this all-important subject are welcome. E. W. GOODALL (*Lancet*, July 2, 1904) states that the most important constitutional symptom is shivering. In 26 per cent. of cases this occurred at almost exactly the same time as perforation. It may be of all degrees of violence up to prolonged rigors. It occasionally precedes all symptoms, including the pain. The author cites a large number of cases which are studied with unusual care. He states in conclusion that inasmuch as everything depends upon early operation which cannot be made without early diagnosis, he would not now hesitate to open the abdomen if there were definite evidence of localized tenderness and rigidity, more especially if there had been shivering, even in the presence of little or no pain. In his opinion, peritonitis very frequently precedes the perforation. Unfortunately, however, the signs of this peritonitis are not at all obvious, so that the preperforation exploration which has been advised does not seem to him practical. Rapidity of the operation is of great importance. This of course hinges upon the early finding of the perforation. In most of the cases, as is well known, perforation takes place within twenty-four inches of the ileocecal valve. In 60 per cent. of 55 cases, it was within twelve inches of the valve. The best incision is in the semi-lunar line below the umbilicus, except in the presence of localizing symptoms when the incision should be made over the site of the tumefaction. The establishment of an artificial anus is to be employed rather than radical operations of gut resection and union, if the perforation is found to be too large to close with a purse-string or Lembert stitch. These methods require so much time that the low vitality of the patient seems in most cases to discountenance them. Inasmuch as there is almost always a certain amount of peritonitis accompanying the lesion, most of these cases should be drained. The author has used local anesthesia in one case only, and this was unsuccessful.

PHYSIOLOGY.

Innervation of the Stomach.—Agreeing with other observers, W. P. MAY (*Jour. of Physiol.*, June 30, 1904) finds that the vagus contains both motor and inhibitory nerves for the stomach musculature. But, at variance with other investigators, he concludes that the splanchnic nerves have no direct influence whatever, either motor or inhibitory, on the muscular wall of this organ. The effect of vagus stimulation in the cardiac and pyloric sphincters is practically the same as in the stomach. First one obtains an inhibitory effect, followed shortly by an augmented effect.

Movements of the Colon.—Antiperistalsis is a characteristic feature of the muscular activity of the colon, according to T. R. ELLIOTT and E. BARCLAY SMITH (*Jour. of Physiol.*, June 30, 1904). The regressive movement of material so produced explains the need of a strong ileocolic sphincter, and is to be correlated with the development of the cecum. Such antiperistalsis consists merely of moving rings of constriction originating in the circular muscle, and not abolished by nicotine. It is not a coordinated movement of contraction preceded by relaxation. A true persistalsis has not been observed to move reversely. The sacral visceral nerves do not control the cecum. Generally their territory is limited to the final part of the colon, wherein they cause both circular and longitudinal muscles to contract. The inferior mesenteric or sympathetic nerves carry inhibitory impulse to the cecum and to the whole of the colon. The latter tends to show a division into three regions of different activities, the proximal, intermediate and distal. These are completely distinct in the herbivorous mammal, antiperistalsis is then confined to the first division; the sacral visceral nerves control only the last.

The Ileocolic Sphincter.—The junction of the small and large intestine is controlled by a muscular sphincter, and not by a mechanical valve, according to T. R. ELLIOT (*Jour. of Physiol.*, May 3, 1904). Stimulation of the sympathetic nerves causes the sphincter to contract, though at the same time inhibiting the circular muscle in the wall of the ileum and colon adjoining the sphincter. In the cat these sphincter fibers issue chiefly from the thirteenth thoracic and first and second lumbar roots. Both anemia and adrenalin produce the same effect as sympathetic stimulation, that is, constriction of the sphincter. Removal of the spinal cord abolishes permanently the power of the sphincter to keep apart the contents of the ileum and colon.

The Adaptation of the Pancreas.—The frequency with which modern physiological research reveals the adaptability of the various bodily organs to changes in the environment or to new uses, is again shown by the recent discoveries of F. A. BAINBRIDGE (*Jour. of Physiol.*, May 3, 1904) on the human pancreas. The following is a summary of the author's conclusions: The pancreas of adult dogs normally contains no lactase, although this enzyme is present in extracts of the intestinal mucous membrane of such dogs; yet when dogs are fed for two or more weeks on a milk diet their pancreatic juice, obtained by means of secretin, invariably contains lactase. The formation of lactase by the pancreas is a specific reaction to lactose; it occurs only when lactose is given by the mouth, and not when it is injected subcutaneously. The lactase of the pancreas is in no way derived from that present in the intestinal mucosa; it is formed by the pancreas itself and represents a definite adaptation to a milk diet on the part of the pancreas. The subcutaneous injection of extracts of the intestinal mucous membrane of a milk-fed dog into a biscuit-fed dog causes the pancreas of the latter to produce lactase. This is the only means apart from a milk diet by which the pancreas can be made to manufacture lactase. Extracts of the intestinal mucosa of biscuit-fed dogs are ineffective. The adaptation of the pancreas to lactose is carried out by a chemical mechanism. Lactose acts upon the intestinal mucous membrane to produce some substance, which is carried in the blood-stream to the pancreas, and stimulates the latter to produce lactase. Secretin appears to have a definite composition, is in no way modified by difference of diet, and is not con-

cerned in the adaptation of the pancreas to food; it calls forth the secretion by the pancreas of all the enzymes present in the gland at the time. The pancreas of new-born puppies contains no lactase, although the enzyme makes its appearance within a few days. It has not yet been determined how far this process is also a chemical adaptation.

Ionic Permeability of the Red Blood Cells.—The red blood cells of man and the frog acquire under the influence of CO_2 electrical properties by virtue of which their enveloping membrane becomes permeable to anions ,according to R. Höber (*Pflüger's Archiv*, March 28, 1904). This permeability to anions does not occur in the absence of CO_2. The production of this condition is brought about by means of the hydrogen ions, whose point of attack are the anodic colloids of the enveloping membrane, which become cathodic. Cations like Fé ††† and Al ††† which act upon anodic colloids similarly to H† produce no anion permeability. The production of the latter process is a reversible one.

Production of Sugar in the Organism from Albumin and Fat.—A critical and experimental research into this problem has been made by E. F. W. Pflüger (*Pflüger's Archiv*, May 25, 1904). In a previous monograph upon the subject of glycogen, the author showed that the production of this substance from proteid has not been proved. Theoretically the possibility of such a transformation is denied, for the structural elements of glycogen are not only uniform among themselves, but are wholly different from those of the albuminous molecule, whose constituents consist of various substances. Pflüger was of the opinion that glycogen is produced probably from carbohydrates or substances closely related to the latter. The author was able to show that in all known investigations the immense culmination of sugar in diabetics is explained by the amount of glycogen stored up in the organism. The above theory of the author was fortified by the fact that the liver cannot prepare glycogen from all forms of carbohydrates. Thus cane sugar and milk sugar, injected into the blood, pass the liver unchanged and are eliminated in the urine. It would only be necessary for the liver to hydrolytically split cane sugar and milk sugar in order to produce glycogen. The liver does not possess this capacity. This would be difficult to understand if the liver had the power of building up glycogen out of the numerous hydrolytic producers of albumin. It has been found that the total extirpation of the pancreas, performed by a careful and skilful surgeon on a well-nourished dog at one sitting is really followed by no diabetes. On the other hand, if the pancreas be removed piecemeal, at several sittings, diabetes will result. What is the explanation of these differences? In the first place one must recognize a condition discovered by Hoffmeister, known as "hunger-diabetes." A dog in whom the nourishment is considerably reduced will eliminate a considerable quantity of sugar. The author explains this phenomenon as follows: The result of starvation is to show the burden of metabolism upon fats and carbohydrates. But inasmuch as fat can be oxidized only after it has been transformed into sugar, it follows that the greater part of metabolism proceeds through sugar. This results in a strain upon these cells that are concerned in the elaboration of sugar with a consequent exhaustion and alteration of function. The quantity of sugar, therefore, which would otherwise satisfy all the needs of nutrition is no longer oxidized and consequently appears in the urine. This form of diabetes occurs without extirpation of the pancreas. In the case of a starving animal, in which the pancreas is partly or entirely removed, a traumatic diabetes, resulting from the operation is added to the starvation diabetes. If, however, after extirpation of the pancreas the animal be fed, the resulting digestion and absorption occasion an increased volume of blood, an augmentation of the work of the digestive cells, and a stronger peristalsis. These conditions powerfully stimulate the numerous wounds in the abdominal cavity and lead to a reflex production of sugar. At the same time the absence of the pancreas impairs the process of digestion and the fats pass largely unchanged with the feces. The author successfully repeated the experiment performed by Seegen and confirmed by Weiss, namely, the formation of sugar by the digestion of liver substance with fat and fatty acids.

Influence of External Hemorrhage on Proteid Catabolism.—The knowledge of the chemical changes brought about in the organism as the result of the loss of a large amount of blood will form an important basis for future clinical and pathological researches along this line. P. B. Hawk and W. J. Gies (*Amer. Jour. Physiol.*, June 1, 1904) found that external hemorrhage, equal to from 3 to 3.5 per cent. of the body-weight, of dogs, produced the following effects: In well-nourished animals, in weight and nitrogen equilibrium, and fed continuously on a diet of constant composition, there was a temporarily increased output of nitrogenous and sulphur containing products in the urine, and a valuable effect on the elimination of phosphorized substances, though mainly a decreased elimination of the latter. Total solids in the urine were increased with the nitrogen and sulphur catabolism. These effects were relatively slight after one bleeding of moderate amount, but became more marked and lasted longer with repeated losses of blood. The increased elimination of the catabolic products occurred only in the urine. The amount, consistency, and composition of the feces were apparently unaffected by the hemorrhage. Digestion did not appear to be materially disturbed at any time, even after several severe hemorrhages at short intervals. There was little or no effect in intestinal putrefaction. Body-weight steadily declined in the original equilibrium diet after each bleeding. When the animal was allowed to eat freely hemorrhages were followed by gradually increased weight. Moderate loss of blood markedly increased the appetite and caused thirst, even during periods when the animal was receiving an excess of food. Excessive losses of blood had apparently an opposite effect. Volume of the urine and its specific gravity fell at first after hemorrhage, then rose far above the average for several days, returning shortly to the usual average. Hemorrhage caused an immediate stoppage of the formation of urine, a subsequent retardation of flow, and finally a decided stimulation. It also inhibited the hypersecretion of saliva during ether anesthesia. There was an occasional glycozuria, due solely to the anesthetic.

The Part Played by Benzine in Poisoning by Coal Gas.—Coal gas produces first excitation and then rigor of the isolated frog's muscle, according to R. Staehlin (*Proc. of the Royal Soc.*, Vol. 73, No. 489). Frogs exposed to coal gas show excitatory phenomena which are absent when the animal is placed in an atmosphere of CO or nitrogen. The specific effects of coal gas in frogs are determined by the presence of benzene in the gas, and can be produced by air containing the same percentage of benzene. There is no reason to suppose that the poisonous effect of coal gas in mammals is determined by anything except its content in CO.

The Physiological Action of Radium.—The effects of this substance on the principal constituents of the body—albumin, carbohydrates and fats—has been studied by J. WOHLGEMUTH (*Berl. klin. Woch.*, No. 26, 1904). He exposed these for a period of from fifteen to thirty minutes daily to the rays and made an analysis at the end of five days. Repeated trials showed that the composition of the materials was unchanged. It was also shown that the elective action on lecithin, as claimed to exist by Schwartz, had no foundation on fact. The effect of radium on tuberculous lungs was studied by exposing them to the radiations, and it was determined that the exposure in an incubator resulted in the absorption of an amount of nitrogen four times greater than that of the control specimen. This is explained by assuming that the resistance to autolysis after death is lessened by the action of radium. If this is correct, then the difference in the amount of nitrogen would become less as the resistance of the control specimen was overcome. This was actually found to be the case, for after ten days the amounts of nitrogen in solution were practically the same in both specimens and continued so.

MEDICINE.

Effects of Endofaradization and Endogalvanization on the Stomach.—A study of the effects of these measures on the gastric secretion, motility and sensibility has been made by A. BORRI (*Deut. med. Woch.*, 1904, No. 26), who also found that the reports made by different sources varied greatly. His own observations were conducted on ten persons, two of whom were practically normal as regards their gastric and intestinal conditions. The aggregate number of individual tests was 106. Regarding the secretory functions of the stomach he found that neither form of current had any effect, the occasional changes in the hydrochloric acid and pepsin contents being attributed by him to the procedures necessitated by the introduction of the electrical apparatus. It was shown, moreover, that the normal stomach, in contrast to the atonic one, exhibited a comparatively greater degree of contraction on application of the faradic current. Disturbances of motility cannot be said to be in any way markedly influenced by the faradic stream. The galvanic current, however, seemed to exert a favorable influence on sensory disturbances of the stomach, and the author feels certain that this effect was gained independent of suggestion. When the negative pole was placed in the stomach a well-marked anodyne effect was noted, but the writer is not prepared to explain this action.

Epidemiology of Typhoid.—It is some fifty years ago since Pettenkoffer advanced his ground-water theory, to explain the occurrence of large epidemics of cholera and typhoid. His theories have not been generally accepted, but now, at last, R. EMMERICH and W. GEMÜND (*Münch. med. Woch.*, June 21 and 28, 1904) have brought convincing proof which shows that the water-supply plays only a subordinate rôle. With high-ground water the germ cannot multiply, since the necessary food-stuffs and air are washed out of the superficial layers, and since the temperature is too low to permit of reproduction. As soon as the ground-water sinks water will travel from below upward by capillary attraction and dissolve the organic and inorganic constituents of the soil; furthermore the pores are filled with air, the temperature is more suited for active growth and the rays of the sun will kill off a large number of saprophytes which would interfere with development. From one focus in the soil the germs are spread by the shoes of those who travel over it, by rats, mice and many insects and worms. These facts can be experimentally proven by filling a cylinder with soil and dipping its lower end into a fluid containing cholera germs in suspension. There will be a capillary flow in an upward direction, and in eleven days the entire column will be infected. If the soil has been washed so that it contains no nutritive material the bacteria die off rapidly. Under favorable conditions the germs do not die off before thirty days; this corresponds with the fact that epidemics generally last thirty-five days. As the cholera germs proliferate downward into the deeper strata of the soil the capillary stream will carry up with it some of the products of their metabolic activity, chiefly the enzyme cholerade, which limits the development in the superficial strata. It is a well-known fact that certain cities are immune from cholera; this is also due to peculiarities of the soil which here is made up entirely of clay, consisting of small, sharp particles which are in constant motion and thus destroy the germs mechanically. Cities situated partly on sand, partly on clay, are only partially immune. The majority of symptoms which make up the disease cholera are merely evidences of nitrite poisoning and depend upon the property of the bacteria to reduce nitrates which occur abundantly in drinking water and many vegetables. Individuals who carefully avoid nitrates will often escape during epidemics. In very much contaminated soil the proportion of nitrates is usually high, and the reducing power of the germs is greatly enhanced where there is an excess of these salts, hence exceptionally severe symptoms can be expected under such conditions. The practical deduction is that proper irrigation of soil during dry weather will be the best safeguard against epidemics.

Virulency of Sputum in Pneumonia.—Since the sputum of severe or fatal cases of pneumonia is highly virulent toward mice, while that of mild cases hardly affects them. D. STÜRZ (*Zeitsch f. klin. Med.*, Vol. 52, Nos. 5 and 6) determined to investigate if the time which elapses before the animals die bears a definite relation to the severity of the disease. In every instance one cubic centimeter of the fresh expectoration was injected subcutaneously. Two different mice, injected with the same sputum, generally died in approximately the same number of hours. In fatal cases the animals lived eight to eleven hours, in cases with doubtful prognosis eleven to twenty hours, and in mild cases twenty to thirty-five hours. The virulency does not fall with the crises, but remains relatively high for twenty-four hours, hence other factors bring about the crisis. With exacerbations the virulency also rises, and since this rise occurs before the appearance of physical signs, it is of considerable practical value. It is thus advisable to inoculate a mouse every morning and evening.

Specific Precipitin Reaction for Bothriocephalus.—A very interesting communication is presented by ISAAC and VAN DEN VELDEN (*Deut. med. Woch.*, 1904, No. 27) on this subject. From a case of *Bothriocephalus latus* infection they prepared a solution obtained by autolysis under aseptic precautions from the fresh proglottidæ. With this they were able to obtain precipitation when added to the blood serum of the patient afflicted with the disease, but failed to get any reaction with the serum of a healthy person. Rabbits were treated with the solution, and the serum from the latter showed similar phenomena. This was confirmed by control tests in normal animals. It appears, therefore, that certain albuminoid bodies pass from the *Tænia* into the patient's circulation, which being in the nature of foreign materials, succeed in producing specific precipitins.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 13, 1904.

DR. GEORGE F. SHRADY.

The resignation of Dr. George F. Shrady, as editor of the *Medical Record,* comes as a surprise to the profession. For thirty-eight years he has conducted this well-known journal, establishing for himself the longest editorial record in the country; and it is with regret that we learn that he is no longer to be the presiding genius of the paper he has conducted from its start.

Through the most exciting years of medical discovery Dr. Shrady has sat on high, watching the scientific heavens for new stars of thought; and the sky has been brilliant with them: Bacteriology, antisepsis, Koch's tubercle bacillus, appendicitis, yellow fever, and others too numerous to mention. Each and all he has recorded year by year, discerning with a keen eye the true lights from the will-o'-the-wisps that flicker over the medical horizon.

His position has been an enviable and an honorable one, that of disseminating new truths to the world, and he has filled it with a dignity and an energy of which few other practising physicians are capable.

Among the many inestimable services that Dr. Shrady has rendered to the medical profession, we single out the high ethical and professional standards of medical literature that he has always proclaimed and practised, and in any controversy in which the honor or the privileges of the profession have been concerned the practitioner of the country has always had a worthy and high-minded, as well as quick-witted spokesman.

The laity who are familiar with Dr. Shrady's name as one of the surgeons who attended President Garfield, and as an authority to appeal to in times of agitation, probably do not realize how much they owe to him directly for his strong influence in civic matters pertaining to health. Much of the excellent sanitary condition of New York City, as well as many matters referred to the Board of Health, owe their existence to his indefatigable energy in pushing reforms through, and in arousing physicians to a sense of their duty. His words, whether written or spoken, have carried authority among the powers that be, and have brought assurance to the readers of the daily press; so that in many crises of the city's development, in scares of cholera, smallpox, plague, his voice has been heard with profit.

That Dr. Shrady should resign his power in the prime of life is a loss to the profession, but it gives him a well-earned rest after what has been a long series of ardent and arduous achievement. We bid him an editorial farewell, feeling with him that the *Record,* which has been the child of his creation, will be in skilled hands, under the editorial direction of Dr. Thomas L. Stedman, and no doubt will continue to occupy the position of prominence that Dr. Shrady has made for it.

INFECTION IN TUBERCULOSIS.

The recent discussion of the subject of infection in tuberculosis at the New York Academy of Medicine (see Society Proceedings in this week's Medical News, page 327) brought out a number of interesting conclusions drawn from recent observations and study with regard to modes of infection and tuberculosis, which should be familiar to all of the medical practitioners of the country.

It seems very clear now that while the infection with tuberculosis by means of inhalation may be an important factor in the production of the disease, there are very striking considerations which make this seem much less than it used to be considered. For example, Dr. Jonathan Wright, of this city, who, as a distinguished specialist in diseases of the nose, throat and larynx, has had many opportunities for the study of this question, does not hesitate to express a reactionary opinion, which must carry no little weight. He consid-

ers that it is practically impossible for dust particles to find their way past all of the protective mechanisms that nature has spread so abundantly before the only mode of ingress to the lungs. After all, it should be borne in mind that all air must, in normal individuals who breathe through the nose, pass through the tortuous nasal passages, which are almost sure to catch and retain any foreign particles that may be in the air. If by chance, however, dust particles or minute globules of expectorated material should find their way past the mucous membrane of the nose, there are still abundant opportunities for them to be caught and retained before entering the lungs. The passage into the lungs is not direct, but almost at a right angle and at every portion of the course, moist mucous membranes are ready to catch dust particles or any other material that may be present. Even if air with infectious material in it should find its way into the pharynx and be carried by the current of air toward the lungs, there still remain the two narrow chinks between the true and the false vocal cords to be passed before they find entrance even to the trachea. The chink of the glottis is very narrow and foreign particles of any kind must find their way through only with the greatest difficulty and by the merest chance.

Even, however, if they find their way into the trachea, this does not assure them direct entrance into the lungs except when the breathing is very deep and fast, for it is only at such times that air is ever carried directly beyond the large bronchi into the smaller air passages. Ordinarily, in quiet breathing, the air currents of respiration do not pass much below the bifurcation of the trachea, and the interchange of gases necessary for vital processes takes place by means of diffusion. The air in the large bronchi is comparatively quiet, and from it any particles that may be present are likely to settle by means of gravity on the moist mucous membranes, where they are retained. From here they are inevitably carried by the ciliary processes of the cells outward, and so there is very little chance of them proving really infectious. Just how, in inhalation, tuberculous infection of the apexes of the lungs takes place is rather difficult to understand. After all, it is too much to think that air containing particles of solid material is carried directly by means of a current into the small alveoli of the left apex, for instance, whose infection is the most frequent initial lesion in tuberculosis.

After comprehending these difficulties as regards inhalation tuberculosis, the recent observations with regard to possibilities of tuberculous infection through the intestinal tract, become even more interesting than they would otherwise be, though they represent some of the most important additions to our knowledge during recent years. Professor von Behring announced not long ago that in calves at least it is perfectly possible for tubercle bacilli to pass through an uninjured intestinal mucous membrane. Other observers have found this same thing to be true, especially when animals are fed rather plentifully on fatty materials. Fat droplets are taken up directly by the mucous membrane and passed on to the lacteals. If these fat droplets contain tubercle bacilli, these are not pressed out during the passage through the mucous membrane. Dr. Ravenel, of Philadelphia, in a series of very important observations on dogs fed with butter, which had been mixed with tubercle bacilli, found the bacilli in the thoracic duct and in various portions of the absorbent system four hours after the animals had been fed. It is easy to understand that bacilli carried up through the thoracic duct and poured into the venous circulation, to be carried almost directly to the heart and thence to the lungs, might very readily, under such circumstances, produce an infection of the lung without giving any sign of the fact that they had obtained their entrance originally into the body through the intestinal tract.

These considerations become of even more interest when it is realized that there is no doubt in the minds of most impartial bacteriologists, at the present time, that bovine tuberculosis may occur in human beings as the result of infection through the intestinal tract by means of food material contaminated with tubercle bacilli from cattle.

Even German investigators have found that, assuming the truth of Koch's principle of the special virulence of bovine tubercle bacilli, in a certain proportion of cases of human tuberculosis the bacilli present were surely of the bovine type. Besides Dr. Ravenel, such distinguished American investigators as Professor Theobald Smith and the late Dr. E. A. de Schweinitz (whose loss to American medicine will be felt nowhere more acutely than just in this subject) found the same thing to be true. There seems no reason to doubt, then, that Professor Koch's announcement of the non-intercommunicability of bovine and human tuberculosis is without foundation in truth and may easily give rise to added

dangers of the contraction of tuberculosis, if it should induce any relaxation of the laws for the protection of human beings against tuberculous infection from cattle either through meat or milk.

In a word, the whole question of modes of infection in tuberculosis is on trial as yet. It is perfectly possible that many of the cases of lung infection may be primary in the lungs and yet the infectious material may have come through the intestinal tract. It must not be forgotten that there is much more danger of dust getting into the mouth and then being swallowed in the sputum, perhaps to escape digestion in the stomach and find its way through the intestinal wall in emulsified fat than there is for it to gain an entrance into the pulmonary tissues when inhaled into the lungs. There is room for further investigation with regard to the occurrence of primary tuberculosis of the thoracic duct and of the possibility of infection through this. Even the occurrence of enlarged bronchial glands is not an absolute sign that the port of entry for the infection was through the larynx and trachea. Every physician who has the opportunity to make autopsies on cases of tuberculosis in an early stage, or on children who have died from tuberculosis, should pay particular attention to these points, since it is possible that much that is of great practical value may be learned from them.

ECHOES AND NEWS.

NEW YORK.

Appointment of Dr. Jenkins.—Dr. William T. Jenkins, ex-Health Officer of the Port and brother-in-law of Richard Croker, has been appointed Sanitary Engineer in the Health Department at $2,400 a year. The appointment was made by Commissioner Darlington from July 1, 1904.

State Experts for the Immigrant Insane.—Dr. Sidney D. Wilgus of New York City has been appointed by the State Commission in Lunacy as chief examiner, under the law passed by the last legislature creating a State Board of Alienists to act in concert with the United States examiners at the port of New York in the inspection and return to their own country of all immigrants suspected of insanity, epilepsy or imbecility. Dr. Wilgus will receive a salary of $5,000. The Lunacy Commission aso appointed as assistant examiners and members of this board Dr. George D. Campbell of New York City and Dr. W. E. Sylvester of College Point at a salary of $3,000 each.

Northern New York Medical Association and St. Lawrence County Medical Society.—It has been decided to hold the meeting of both these medical bodies on October 18, 1904, at Ogdensburg, N. Y., the Northern New York Medical Association holding session during the afternoon and the County Society during the evening of the same day. The afternoon session will be held at the St. Lawrence State Hospital, upon the invitation of the Superintendent, Dr. R. H. Hutchings. The evening session will take place in the City Hall. Following the evening meeting a banquet will be held under charge of both societies. This arrangement will permit members of either society to attend both meetings and it is desirable that the members cooperate as far as possible to make this union meeting both pleasant and profitable by their attendance and participation. It is also urged that members who will present papers notify (giving title) the president of their respective society on or before July 25, in order that a provisional program may be prepared at an early date. Members are urged to present for the benefit of the Society any interesting cases occurring in their practices.

Cost of Tuberculosis in This City.—New York loses $23,000,000 annually through tuberculosis, according to Dr. Darlington. "Estimating the value of a single life at $1,500—not necessarily a high estimate—and taking only those lives between sixteen and forty-five years," said Dr. Darlington, "the loss of life in this city alone from tuberculosis mounts up to the startling sum of $23,000,000 annually. The death rate here is much lower than in large European cities, which shows what has been accomplished by the spread of clinics and of preventive measures, of better housing conditions, of the warfare against dark, interior rooms, and unsanitary plumbing which has gone forward here during the last few years, yet the death rate will not go much lower with us unless we take even more radical steps. It is a question simply of educating the people and of general sanitary conditions. The general sanitary conditions are still bad in New York, and the inflow of immigrants who must be educated in right living is constantly increasing. Sometimes we may feel discouraged, but the fight is a good one, and I have infinite faith in the future. We not only know more about consumption, but we are applying what we know more sanely and searchingly."

Beta-Naphthol in Milk.—The New York Board of Health is closely examining samples of milk suspected of containing a new preservative which has been said to cause much illness. The drug is beta-naphthol, a coal tar product, according to the *Times*. Our Health Board says: "They are a little afraid of our rigid examinations here in New York. Nearly all of these adulterations which are tried outside fail to come here. We do have adulterations here, too, of course, but they are not so plentiful as elsewhere. We are constantly endeavoring to keep down the death rate of infants in the Summer, but our observation teaches us that more deaths are caused from a lack of cleanliness than from adulterations."

Receptions to Sir Felix Semon.—Sir Felix Semon, D.V.O., physician extraordinary to the King, who is to deliver the address on Laryngology at the St. Louis Congress of Arts and Sciences, will arrive at New York early in September. He will be the guest while in New York of his life-long friend, Prof. George M. Lefferts, and also of Dr. Emil Mayer, who is associated with Dr. Lefferts as co-editor of the *Internationales Centralblatt für Laryngolagie*, and of which Sir Felix has been editor-in-chief since its beginning twenty years ago. The American tour, which has been arranged by Dr. Mayer, will consist of a visit to Niagara Falls, thence to Chicago, where

Prof. E. Fletcher Ingals and the Western Laryngologists will entertain both Sir Felix and Lady Semon, who accompanies him. At St. Louis the address is to be delivered, for which purpose he was specially invited. During his stay there, Dr. M. A. Goldstein, editor of the *Laryngoscope*, will be his chief entertainer, assisted by his fellow Laryngologists. Sir Felix and Lady Semon then travel to Washington, where Dr. J. H. Bryan will see to their comfort. Philadelphia is the next stop, where Lady Semon has relatives. At Montreal, where the travelers will be the guests of Dr. and Mrs. H. S. Birkett, Sir Felix will take a four weeks' hunting trip, as the guest of Sir Thomas Shaughnessy and the Canadian Pacific Railway, returning to New York City October 31, to remain a week before sailing for home. This last week is apt to be a busy one for them, as the program consists of a dinner under the auspices of the Laryngological Section of the New York Academy of Medicine, an address on Malignant Diseases of the Larynx at Hosack Hall, by invitation of the same section, functions on different evenings to both by Dr. Lefferts, Dr. Emil Mayer and Dr. Thomas R. French of Brooklyn.

The Lying-in Hospital.—During the month of July the Lying-in Hospital has had 556 applicants for treatment, of whom only 181 could be admitted and cared for in the hospital. The number of children born in the hospital during July was 137. For the same period in the outdoor department 334 persons applied for assistance at their own homes and 278 were treated in confinement. The number of medical visits made was 1,304. Through the Ladies' Auxiliary 1,726 garments were distributed and 232 patients supplied with care-takers. The auxiliary also gave coal and other articles and made 1,287 visits to assist and aid. The Diet Kitchen distributed tea, coffee, bread, sugar, oatmeal and milk. The work of the Lying-in Hospital is increasing rapidly, but the number of patients received is still limited to one-third of its actual capacity, owing to lack of means to open additional wards. As large a number of students as can be admitted are now receiving training in obstetrics, and some 50 nurses.

Typhoid Epidemic Near Jerome Park Reservoir.—The authorities of the Health Department admitted yesterday that there was an epidemic of typhoid fever in the Bedford Park section of the Bronx, and that the condition of affairs there was becoming alarming. Forty-two cases of typhoid were discovered in one block alone, and so far as could be learned last night nearly all of the persons afflicted with the disease were stricken after drinking water from a spring which empties into the uncompleted Jerome Park reservoir. This reservoir was soon to be put into use as a storage reservoir for the water supply of the Borough of Manhattan, but at present it contains no Croton water, and there is no danger of the epidemic spreading to Manhattan. The disease is now confined to a district which practically abuts upon the new reservoir at Jerome Avenue and One Hundred and Eighty-fourth Street, where the contractors engaged in completing the reservoir are at work blasting rock. Dr. Charles T. Roberts, the Sanitary Superintendent of the Health Department, and his assistant, Dr. Charles F. Spencer, accompanied by several other physicians, went to the typhoid district yesterday and made a thorough investigation of the conditions. They learned that all of those who are now suffering from the disease had partaken of water from a near-by spring which forms a creek running through the new reservoir. Samples of the water from this creek, from the spring directly, and portions of the muddy soil there were carried away by the Health Department officials for analysis.

PHILADELPHIA.

New State Journal.—*Sanitation*, a monthly journal of hygiene and sanitary science, has begun publication, No. 1, Vol. I, being issued in July. It is to be the official bulletin of the State Board of Health of Pennsylvania and of the Associated Health authorities of Pennsylvania.

Report of School Inspection.—During April, May and June, the months first devoted to the inspection of public schools, 155,707 children were examined and 6,936 excluded because of disease. The eyes of 5,150 were found to be affected, 1,807 being obliged to wear glasses. The work of the new corps of inspectors has been entirely satisfactory to the Health Department and the Board of Education. The health of pupils is noticeably improved as a result of inspection.

To Enforce Vaccination.—The fifty medical inspectors of the city are making a house-to-house canvass to vaccinate all people. The names and addresses of those who refuse, together with their employer and physician, are registered at the department. In each case the physician and employer are notified of the refusal. The employers are notified that every store, mill, manufactory, hotel or church in which a case of smallpox is found will be closed for fumigation.

To Stop Assaults.—The Bucks County Medical Society, at their meeting of August 3, discussed at length the subject of assault upon women which are of late becoming so frequent. The sentiment of the society was shown by the unanimous adoption of resolutions asserting the necessity of the most drastic punishment in the case of men convicted of criminal assault and endorsing the bill drawn by Senator Grimm providing castration as the punishment of such offense.

Sanitary Rules Changed.—The Department of Health and Charities will on September 1 put in force new rules governing house drainage, ventilation and cesspools. Plumbers must register annually and place a sign to that effect before their place of business. Outside closets flushed directly from the water supply pipes are to be done away with. Wooden bath tubs are also prohibited.

CHICAGO.

Hospital Accommodation Given by Sanitarium.—The Sisters of St. Anne have completely isolated one wing of their sanitarium for consumptives at Forty-ninth and Thomas streets. They have fitted up operating and dressing rooms and are now taking general medical and surgical cases. The hospital building was erected only a few months ago, and is equipped with all modern appliances.

Illinois State Board of Health Report on Drainage Canal.—The Illinois State Board of Health, in a recent report, summarizes the results of the investigations made by the board to determine the sanitary effect of the new flow southward from Lake Michigan. That the waters of the canal in no wise contaminate the water supply of towns along the Illinois and Mississippi rivers is not only the firm conviction of the Board of Health, but it also is its opinion that the waters of those streams are actually benefited by the added flow coming down from Chicago. Mingling of the canal waters with

those of the Missouri, from which St. Louis draws her supply, would furnish an improvement which could not well help pleasing the consumers of the river towns, in the belief of the board.

Summary of Report.—The conclusions reached by the health officials in their long search into this question are summarized thus: That the water of the Des Plaines and the Illinois rivers is purer and better since the opening of the canal on account of the large amounts of pure lake water coming through the canal and diluting the sewage in these streams. That the water of the drainage canal in its present condition probably is purer and better than the water of the Illinois river at low stage. That a great part of the contamination of the Illinois river comes from the drainage from farms and villages and the sewage from cities and refuse from manufacturing industries along its shores, and that the water of the drainage canal actually improves these waters by the dilution of this original contamination. That the water of the Illinois river above its mouth is purer and freer from contamination than is the water of the Mississippi river into which it flows. That the water of the Missouri river above its mouth shows evidence of more serious sewage contamination than does the water of the Illinois river above its mouth, and that the Missouri river water, instead of being contaminated by the water of the Illinois river, with its burden of Chicago sewage, actually would be improved by it. That farm, village and city drainage is a serious source of contamination to streams, and that the Missouri river drains a larger area than the Illinois river, and, further, is badly contaminated by the animal refuse from the packing industries of Kansas City and Omaha. That the city of St. Louis takes its water from a point on the west side of the Mississippi, but a short distance below the mouth of the Missouri, and that the great bulk of the St. Louis supply is taken from the Missouri river water.

Illinois Pure Food Law.—It is a tribute to the advancement in knowledge of dietetics to have pure food laws on the statute books of the State, but unless they are enforced they afford little or no protection to the people. State Commissioner Jones of Illinois has been annually vigorous in prosecuting manufacturers of food products, and it is said that already suits have been brought against two hundred dealers and manufacturers for alleged violations of the pure food law. Many of the suits charge false labeling, while the bulk of them allege adulterations of the most injurious character. Among the adulterations found are "process butter," impure maple syrup and spurious vinegar. The belief is prevalent that Illinois affords a rich picking for dealers in and manufacturers of food frauds. That this belief is well founded there can be no doubt, from the fact that one hundred of these suits are against Chicago and Cook county dealers, showing that the metropolis, with its two million consumers, offers a market for food adulteration and misbranded food products so large as to defy the efforts of the most watchful and energetic food commissioner and food inspectors.

New Buildings at Dunning.—Four of the buildings authorized by the people of Cook county, when they approved the recent bond issue of $500,000, have been completed. They are the Home for the Cure of Tuberculosis, which has taken the place of the old consumptive hospital, and three cottages for the treatment of insane persons. The Home for the Cure of Tuberculosis was built after a careful investigation along the newest lines for the treatment of the disease. It has grown to such large proportions, especially in congested districts of large cities, that it has become a matter of the greatest importance to meet it, and, as far as possible, suppress it. This is being done; first, by systematic education in the houses of the poor; secondly, by a separation of the moribund cases from the hopeful cases, and, thirdly, by what is known as the outdoor treatment for cases that are hopeful.

Cottages for the Insane.—The cottages for the insane represent the newest type of hospital treatment. They are large, sunny and airy, and are without the prison-like bars on the outside of the windows. The living rooms are separate from the dormitories, and in all respects the cottages look like and are conducted much like private residences. These three cottages are connected by an ornamental colonnade. They are of pleasing architecture, and they make an ornate head for the avenue of cottages at the Dunning institutions.

Employment of the Insane.—In addition to the three new cottages, the large farm cottage is now nearing completion. This is designed for patients who are able to work on the farms. It is supplied with all modern facilities, including shower baths, and is really a part of the new treatment for the insane people, which provides moderate employment for them instead of forcing them to remain idle.

Laboratory Building Under Erection.—Still another building at Dunning is now under erection, the foundation already being in, to provide adequate morgue facilities and room for the pathological laboratory and for clinical lectures. The lectures will be conducted in an amphitheater. The facilities afforded in this building will attract students of medicine and will also cause experts in various diseases treated there to visit the institutions to lecture to doctors, internes and attendants, and in that way improve the medical service to the poor.

Children's Building.—Work has begun on the Children's Building at the County Hospital. This will be a large, roomy, fireproof structure, built on the most modern lines for the treatment of sick children.

New Ophthalmological Journal.—*Ophthalmology* is the name of a new quarterly journal, the initial number of which will appear October 1, 1904. As the title indicates, it will be an ophthalmic periodical of about 250 pages, devoting about one-third of each issue to original essays, the balance to abstracts of original articles appearing in domestic and foreign literature, also complete book reviews. The following well-known opthalmologists and editors are in charge of the various departments: Dr. H. V. Wurdemann, Milwaukee, managing editor and publisher; Dr. Nelson M. Black, Milwaukee, assistant editor; Dr. Charles H. May, New York City, American and English literature; Dr. Casey A. Wood, Chicago, Italian literature; Dr. Charles A. Oliver, Philadelphia, and Dr. Blencowe E. Fryer, Kansas City, French literature; Dr. Albert B. Hale, Chicago, Spanish and Portuguese literature; Dr. Edmond E. Blaauw, Buffalo, Dutch literature; Dr. Charles Zimmermann, Milwaukee, and Dr. William Zentmayer, Philadelphia, German literature; Dr. J. Guttman, New York City, Hungarian and Austrian literature; Dr. Frank Allport, Chicago, British colonial literature; Prof. Dr. M. Wicherkiewica, Cracow, Austria, Polish, Russian and Scandinavian literature; Dr. Mitsiyasu Inouye, Tokio, Japan, Japanese and

Asiatic literature; Dr. Claud Worth, F. R. C. S., London, Eng., English literature.

War on Consumption.—The secretary of the Illinois State Board of Health, Dr. J. A. Egan, has just issued a circular on "The Cause and Prevention of Consumption." The circular is written for the layman, not for the medical man, and it is designed as a plain and practical talk to the consumptive on how he may regain his health and how he may prevent conveying the disease to others; to the healthful man on how he may avoid acquiring the disease himself and how he may appreciate the physical conditions which indicate the threatened invasion of the disease; to members of families of consumptives, advising them as to how they may properly care for consumptives with little danger to themselves and how they may safely continue to live in houses in which consumptives have lived or died, or even sojourned.

No better excuse for this circular need be given than the statement that in 1903 over 7,000 people died from this one disease in Illinois, more than died from typhoid fever, diphtheria, scarlet fever, all forms of bronchitis, influenza, whooping cough, measles and small-pox combined, and that of all these deaths consumption is the one great enemy of the man in the prime of life, killing, without respect to manner of life or social condition, at the age when man is of the most value to his family and to the State. Of the 7,000 dead from consumption in 1903 in Illinois 4,500 died between the ages of twenty and fifty years. In the prevention of consumption the circular especially points out the fact that the spitting of consumptives is the chief source of infection and it urges strongly that healthful persons should not spit in public places or on floors and that they should not permit others to do so. Other important advice in the matter of prevention is: "Don't wear skirts which sweep the infection of consumption from the sidewalks into your homes. Don't put in your mouth things that are promiscuously handled by others. Don't fail to wash your hands before you eat. Don't drink from a glass, cup or vessel used by others unless it is carefully washed. Don't live, sleep or work in a room where there is no fresh air. Don't neglect a cough or cold." Such circulars are useful and might be distributed widely by other State health boards to advantage in the now well-recognized state of "War against Tuberculosis."

GENERAL.

Physicians in Cuba.—Physicians are scare in Cuba; $316,000 worth of patent medicines were imported during the fiscal year 1902-1903, mostly from France.

Five Millions for Hospitals.—What Londoners spend annually on doctors will probably never be known. But the report annually issued by the Metropolitan Asylums Board shows that they expend more than a million a year on the public treatment of imbeciles, the infectious sick and the incidental establishment charges. Moreover, the sum, like the population, is annually increasing. Last year it was £1,123,130 (equal to a rate of 6.65d. in the pound), in 1902 it was £1,013,120, or a rate of 6.08d.

New Hospital for Orange.—Bishop O'Connor has authorized the Rev. F. Victor Romanelli, rector of the Italian Catholic Church of Our Lady of Mount Carmel, to open a hospital for patients "irrespective of race, religion or color." The institution will be under the care of the Sisters of the Most Precious Blood, and will be known as Mount Carmel Hospital.

Rocky Mountain Interstate Medical Association.—The next regular meeting will be held at Brown Palace Hotel, Denver, Col., September 6 and 7, 1904. The following preliminary program is announced: W. W. Grant, Denver, Complications and Sequelae of Appendicitis; S. C. Baldwin, Salt Lake, Hip Joint Disease; John C. Munro, Boston, Report of Cases of Operation Upon the Lung; D. S. Fairchild, Des Moines, Pregnancy Complicated by Tumors of the Uterus; Charles H. Mayo, Rochester, Minn., Peritoneal Tuberculosis; James R. Arneill, Denver, "Hyperchlorhydria," A Common Expression of Neurasthenia and Allied Conditions; J. N. Hall, Denver, Report of Eight Cases of Pernicious Anemia; A. C. Ewing, Salt Lake, Typhoid Fever; George H. Stover, Denver, X-Ray Treatment of Urethral Carbuncle; A. A. Kerr, Salt Lake, Ectopic Pregnancy; George C. Stemen, Denver, Shock; Edward C. Hill, Denver, The Chemistry of Drug Action. One and one-fifth fare for the round trip in Colorado has been obtained and proportionate concessions for outside States are expected.

National Jewish Hospital for Consumptives.—The National Jewish Hospital for Consumptives, in Colorado, has just completed another fiscal year, during which it cared for 165 patients of all creeds and from every section of the Union. Since its establishment in 1900 it has cared for 554 consumptives, the larger percentage of whom left the institution either cured or much improved. At present the facilities of the hospital are taxed to their utmost, and there is need for an enlargement of the institution, which is free to patients.

Japanese Surgeons and the War.—An interesting article appears in the *Deutsche Medicinische Wochenschrift*, which is abstracted by the *Evening Post*. The author is Dr. Wada, a surgeon in the Japanese navy and chief medical officer of the Red Cross Hospital at Chemulpo, in Korea; his patients were Russian sailors wounded in the naval battle of Chemulpo, where the Korietz and the Variag were destroyed. Of the Russian crew 100 were wounded, the majority being taken on board the French cruiser Pascal and the others on board British and Italian men-of-war. The wounded Russians at first declined to leave the French ship, but eventually twenty-four of them were taken ashore. They told the Japanese surgeons that the hospital arrangements on board the Russian ships were very defective, and that there were only five hospital beds for a crew consisting of 26 officers and 556 men. The Russian medical officers, they declared, were so perplexed by the suddenness of the action that they could scarcely attend to the wounded, and the chaplain was intoxicated during the battle. Moreover, the conditions experienced on board the French vessel were not of the best, the patients being placed in a small, damp room and supplied with inadequate food. The condition of the sufferers confirmed this account, for some of their wounds were gangrenous. Dr. Wada says that the Japanese shells exploded when they touched water or the human body and burst into 1,000 small pieces without evolving noxious gases. In most cases the fragments of shell had been removed by the French medical officers, but there were a few patients from whom Dr. Wada withdrew pieces of iron of the size of a small finger. The wounds were nearly all complicated by fractures of the bones, but there was only one instance in which a fragment of shell was found in a bone. The Japanese showed more courage than the Russians.

Medical Training in Japan.—Among the students at Roanoke College, Virginia, in 1889-90 was Hidel Fukuoka, a son of Viscount Takachika Fukuoka, a member of the Imperial Privy Council of Japan and ex-Minister of State for Education, writes a correspondent to the *Evening Post*. One day this young man handed me a copy of the English edition of the catalogue of the Imperial University of JaJpan at Tokio for the session of 1887-88. I examined this catalogue with a great deal of interest. I observed that in each of the six faculties of the university there were professors, native and foreign, who had won the degree of doctor of philosophy from the leading universities of Europe and America. I was especially struck with the advanced character of the College of Medicine, which had a required course of four years of ten months each, when at that time I believe no medical school in our country required more than three years for graduation. After completing the required course of four years, candidates for the degree of doctor of medicine are required to spend some months of the following session at the university to take their examinations. This ordeal covers in all twenty-five days, the examinations being conducted by a committee of the medical faculty. Each candidate is required to diagnose and treat from day to day several cases in the various hospitals of the university. With such thorough and practical training as that, is it any wonder that the field hospitals of the Japanese were highly successful during their war with China? The experience gained then has enabled the Japanese surgeons to make their hospitals even more efficient during the present conflict with Russia.

English Public Houses and Tuberculosis.—The London *Lancet* speaks authoritatively on this subject as follows: "That the public house is a fruitful source of infection by the tubercle bacillus is well known, and the returns of the English registrar-general show that public house servants are specially prone to be affected by pulmonary tuberculosis. This is not to be wondered at when one considers that the floor of the lower class of public house is covered with sawdust which in great measure is impregnated with sputum. This dust dries and is constantly being stirred up by the feet of drinkers. Not only are barmen and barmaids and the customers of the house thus exposed to infection, but the unhappy children who are brought into the house by their mothers are likewise in danger. The public house is the poor woman's club where she can discuss with her neighbors social and domestic incidents; the children cannot be left at home, and so they sit on the public house floor during their mothers' gossip time. Only the other day, passing a large public house in one of the main thoroughfares of St. Luke's, we noticed through the open door of a public bar several slatterly women drinking at the counter, while crawling on the floor of the bar and rubbing their hands in the sawdust with which it was strewn were two babies of from eighteen to twenty-four months old. That this is not an uncommon occurrence those who have occasion to visit poor and squalid neighborhoods well know, and in the light of such facts is it to be wondered that the race is said to be degenerating or that medical science should have such a hard uphill fight with disease? Granting that these children, probably the offspring of degenerate beings, become infected with the bacillus of tubercle, the environment in which they live will necessarily be a potent factor in the development of pulmonary tuberculosis, and not only will they themselves suffer, but they will also involve the public in great expense for their subsequent treatment and keep. Recently a law has been passed to prevent children under a certain age from obtaining intoxicants, and there is legislation for the prevention of cruelty to children, but as yet there is no law to prevent ignorant mothers from leaving their offspring to play on the disease-laden floor of a public house. Efforts are being made to inculcate the precepts of hygiene at an early age, and many publicans, notably those in the borough of Woolwich, post up notices requesting their customers not to spit. But until spitting on the floor of a tavern is made a penal offence, as it is at present to spit in a tramcar, there is but little hope of amelioration."

OBITUARY.

Dr. F. F. Cassaday, senior practising physician in Frankford, died August 3 of apoplexy. He was stricken the day before while alighting from his carriage. Dr. Cassaday was born in Philadelphia and graduated from Jefferson College in 1867.

Dr. Robert Milbank, sixty-six years of age, a well-known practising physician of 154 West Forty-eighth street, New York, died suddenly on Thursday night of apoplexy. Dr. Milbank was a member of the County Medical Society, the Academy of Medicine, the Society of the Alumni of Bellevue Hospital, the Medico-Legal Society, the Northwestern Medical and Surgical Society and was lately a visiting physician to the New York Infant Asylum.

Dr. Orlando Brown, brevetted brigadier-general for services in the Civil War, and for many years one of the foremost physicians of Litchfield county, Conn., is dead at his home residence in Washington, Conn., aged seventy-seven years. He had been ill several months. Dr. Brown was a graduate of the University of New York and the Yale Medical School. His military career, which was distinguished, began in 1861, when he entered the army as assistant surgeon of the Eighteenth Massachusetts Volunteers. Later he became inspector of hospitals and superintendent of the general hospital at Newport News, Va. He was in charge of the welfare of the colored people south of the James river in 1863, and in 1865 was made colonel of the Twenty-fourth Regiment, United States colored troops. In 1866 he was brevetted a brigadier-general for gallant conduct in the service, but resigned his commission in 1869, and resumed the practice of medicine in this place.

Sir William Mitchell Banks, the well-known surgeon, is dead. He was a Scotchman by birth, but the greater part of his life was spent in Liverpool, and his most notable work was the resuscitation of the Medical School of that city and the foundation of the University College there. He was one of the leaders of the present movement which has for its object the discovery of a cure for cancer. Born at Edinburgh in 1842, Sir William took his M.D. degree at the University of Edinburgh. After acting as Demonstrator of Anatomy at the University of Glasgow he removed to Liverpool in 1866. In 1897, when the British Medical Association visited Montreal, Sir William was president of the Surgical Section, and delivered the address on surgery. He was a Fellow of the Royal College of Surgeons and was knighted in 1899.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.[1]

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

FIRST DAY—*Continued.*

(Continued from Page 285.)

Cerebral Infection.—This was the general topic of the Address in Surgery, by Sir William Macewen, F.R.S., Regius Professor of Surgery in the University of Glasgow. The first point taken up referred to the localization of brain abscess. Prior to the advent of cerebral spinal surgery in its later development, abscess of the brain was regarded solely as of a pyemic nature, occurring by metastasis, and, owing to the aberrant manner in which abscess formed, its localization was regarded as impossible, except in the few instances where abscess happened to occur in parts which gave rise to functional manifestations. Such was the old view, but early observation showed that this view was untenable. It was seen that all brain abscesses arising from the foci within the cranium were, if not in direct contact with such foci, at least in contact with the infected path which lay between the primary focus and the abscess. If the cerebral abscess remains unrelieved and continues to grow, it may by extension implicate other regions of the brain distant from the primary external focus, even then the contiguity of diseased structure is generally traceable. So that, by way of illustration, if one takes intracranial abscess resulting from ear disease, one knows that such abscess will form within a limited area of the middle ear, the particular direction of the extension being determined by the anatomical condition of the parts and the direction of the prior pathological encroachments. The abscess will be found either within the temprosphenoidal lobe contiguous with the infected tissue round the sigmoid sinus or in the cerebrum in touch with the infected path from the tegmen antri or tympani, the pathological processes having generally prepared the way and having left in most instances an easily traceable path. This being correct, it must be apparent in a case of abscess of the brain that preliminary investigation is facilitated and the treatment simplified as access to the abscess in either position may be had by extension of the aperture already made in the mastoid.

Abscess versus Meningitis.—Anatomical features are often secondary determining factors between abscess and meningitis, and in the latter case between localized and generalized lesions. If the access of the pyogenic organisms has been by way of the tegmen or the sigmoid, abscess of the brain or cerebellum is frequent; and if meningitis results, it is at least primarily localized, often the result of a soldering process, does not immediately involve vital structures, and is often amenable to prompt treatment.

Abscess Does Not Occur by Pyogenic Organisms Traveling by Way of Internal Auditory Meatus.—If, on the other hand, the pyogenic organisms have traveled by way of the internal auditory meatus, they occasion leptomeningitis of a serious kind on account of its being basal, early involving the medulla and respiratory centers; and, secondly, on account of its inaccessibility. Abscess of the brain seldom or never occurs by pyogenic organisms traveling by way of the internal auditory meatus. His own persoinal observation had never shown a single instance of such an occurrence, nor would it be likely to occur from the anatomical features of the parts. The brain is kept apart from the original pyogenic focus by the whole length of the internal auditory canal, while the expansion of the brain membranes which ensheath the nerves in the canal dip right into it. The leptomeningitis is thus set up in the canal, and from there spreads over the basal membranes. Collections of purulent matter are frequently in the meshes of the pia and arachnoid, and occasionally they produce a softening and ulceration of the brain surface, but not abscess of the brain.

Patients affected with tubercle of the middle ear, with rupture of the membrana tympani, are subject to secondary pyogenic invasion, which runs a rapid course, the pyogenic organisms finding abundant pabulum for their development.

Miliary Tuberculosis from Middle Ear Through Sigmoid Sinus.—Another mode by which tubercle of the mastoid may become a menace to life is by dissemination through the sigmoid sinus to other parts of the body. On many occasions, tuberculous masses of granulation tissue issuing from the mastoid have surrounded the knee of the sigmoid sinus and in a number of the lumen of the sinus has been invaded by the tuberculous granulation tissue.

Reflexes.—The author then spoke of the influence of anesthetics on the reflexes and the persistence of many of the genital reflexes, even under the influence of profound anesthesia.

Cauda Equina Lesions.—Operations were performed in two cases which came under observation of lesion in the lumbar region implicating the cauda equina. Both were affected with pudic paralysis, and in one the anesthetic area extended to the back of the thighs and the soles of the feet, showing the further implication of the second and third sacral nerves. These operations resulted in the restoration of function of the bladder and rectum in both, and of sexual power in one and partial restoration of it in the second. One of the cases was of injury of two months' duration, while the other was of six months, and in the latter the spinal canal was found partly filled with a fibrous tissue mass in which the cords of the cauda equina were adherent on their posterior aspects.

The Voice and the Pudic Nerves.—In two cases where the pudic nerve was affected, among the minor defects attending their condition the patients asserted that their voice had altered since their injury. There was no available means of testing the accuracy of this statement, though one of the patients operated on remarked, some time after the restoration of the pudic functions, that his voice had regained its original "fulness." Doubtless the restoration of the bodily tone and vigor would have an effect upon the voice apart from any direct nervous influence through the vagus to the laryngeals. The assertion on the part of the patients, however, awakens the thought of the possibility. The effect of early castration is well known to produce an imperfectly-developed larynx and a high-pitched voice. But the spermatic plexus is totally different in origin from the pudic, being derived from the sympathetic through the aortic and renal plexus. It is possible that, among the fundamental changes induced by castration, the one affecting the larynx may pass through the pudic nervous mechanism, which must also suffer from the want of development?

Suture Materials.—He then took up the subject of suture materials. The aim in choice of a ligature should be to obtain one which would accomplish the first two objects—namely, to produce a solution of continuity of the internal coat of the vessel and to main-

1 From advance sheets of the *British Medical Journal*, by courtesy of the editors.

tain the parts in apposition for a time sufficient to enable the living tissues to accomplish the organic union of the vessel wall; and thirdly, having accomplished these two former objects, to permit itself to be speedily removed from the tissues without disturbance, its place being taken by a new formation of living connective tissue which would further strengthen the occlusion of the vessel at the part ligated. Asepticity is by many considered the sole requirement in a ligature, otherwise mechanically suitable, but asepticity is only one of the requirements. A further requirement which a ligature ought to possess, is that it will remain in the tissues for a time sufficient to effect its purpose. and which will then be capable of rapid elimination. The same desiderata are required for sutures. A material capable of maintaining the tissues in contact, sufficiently strong to enable the tissues to proliferate and to effect a living union of the parts is required, and after this has been accomplished this suture material ought to become eliminated without disturbance of the parts. So that when the mission of the suture has been accomplished, it should no longer remain in the tissues, a useless dead material capable of producing irritation, but should permit itself to be speedily removed.

Some conceive the idea that it would be good to have a material by the aid of which the parts could not only be brought together, but one which would maintain them in permanent apposition. Such physical union is readily produced between two inorganic substances, such as two plates of metal, but it cannot be obtained between two pieces of living tissue. Living tissue can only be made to adhere permanently by a living bond of union. A suture of dead tissue can only secure coaptation of two living surfaces for a limited period—a period sufficient, in the majority of instances, to enable the living tissues to become united. When such union fails to be produced from any reason the living tissue gives way by absorption in front of the pressure exerted by the dead suture. This absorption goes on until there is no more traction by the suture—until a position of rest is obtained when the suture lies loose in the tissues. When this stage has been reached the dead suture is of no further service—it remains at best a useless foreign body, which, if encapsulated, may be innocuous; but its presence among tissues subject to movement is often a source of irritation, and sometimes of danger, to the neighboring parts (as in hernia). It is sometimes extruded from the tissues by a process of molecular disintegration occasionally associated with abscess formation. He deprecated the use of wire ligature material.

From the foregoing it must be evident that the material to be used for ligatures and sutures, besides being physically fitted to perform its function, requires to be rendered aseptic, and, further, requires to comply with a physiological test. First, it must remain intact in the tissues until its object be accomplished; and, secondly, after that has been attained, it must permit itself to be quickly removed by absorption. Sterilized silk is practically non-absorbable. It resists the action of the tissues for a very long period—years—and is frequently extruded. Silkworm-gut and hair are proof against absorption, and have been removed from the tissues five and seven years after their introduction, and were at the end of that period found to have preserved their smooth surface quite intact. Tendons of deer and kangaroo, though absorbable, resist the action of the tissues for many months. One knows how difficult it is to promote absorption of a sloughed tendon exposed in a wound. Long after the surrounding soft tissues are ready to unite, they are retarded from doing so by the presence of dead tendon. Catgut is one of the best substances generally available for sutures and ligatures, but care ought to be exercised in choosing good material. For ligatures and sutures raw catgut ought to be selected, preference being given to such specimens as present the best physical properties and show that care has been bestowed on its manufacture. It must be evident that the subsequent preparation does not remedy physical defects originally in the gut. such as want of strength, or roughness. The gut must not be hardened in such a manner as to prevent leucocytal penetration. otherwise it will be too resistent, and in this way may be no better than silk or wire.

Dr. Macewen then discussed in detail some of the procedures in the preparation of various forms of catgut, and spoke of the causes of retardation of absorption.

(To be Continued.)

NEW YORK ACADEMY OF MEDICINE.

Section on Pediatrics.

Stated Meeting, held Thursday, April 7, 1904.

The President, Andrew H. Smith, M. D., in the Chair.

The scientific business of the evening consisted of a symposium on methods of infection in tuberculosis, with special reference to children, and was held under the auspices of the section on pediatrics.

Modes of Infection in Tuberculosis.—Dr. Philip S. Sabine discussed the possible modes of infection and suggested that at certain ages particularly people were more susceptible and that infection seemed to occur more readily. For this reason, as pointed out by Dr. Jacobi, the tuberculin treatment had never been a success in children suffering from tuberculosis. Direct inoculation with tuberculosis Dr. Sabine considers not to be so rare as is sometimes thought. Genito-urinary infection with tubercule bacilli occurs directly through coitus and, in Dr. Senn's opinion, is not infrequent from this cause. The frequency with which tuberculous epididymitis occurs in the male, shows the danger to which the female is exposed from this cause. In butchers, anatomists and workers in laundries, direct contagion through wounds with tubercle bacilli is not infrequent. In four reported cases, skin tuberculosis has developed in tattoo marks. In three of these cases the tattooer was actively tuberculous and in the fourth case the person tattoeed was so.

Circumcision Tuberculosis.—There are many cases of tuberculosis reported as occurring in the wound made for circumcision. The old rubrical method, according to which the bleeding was stopped by pressure with the lips, is undoubtedly the reason for the frequency of this form of tuberculosis. It is very evident then that the saliva of persons suffering from tuberculosis may constitute a source of skin tuberculosis, if it should be brought in contact with open wounds. Under almost corresponding circumstances a number of cases of tuberculosis have been reported as occurring in children in whom efforts at resuscitation were made by direct mouth to mouth inhalation. Other forms of direct inoculation of tubercle bacilli into the skin have been reported from wounds made by spittoons, and in four cases reported Czerny as the result of skin grafting. This form of inoculation is not, however, very frequent since of 160 workers, in an abattoir only seven had lesions of this kind. It seems very clear, however, that fingernail abrasions may cause tuberculosis of the nose.

Adenoids seem to be especially liable to infection either from the finger or from instruments used in their removal. This seems to be due to a lack of resistive vitality on the part of the spongy material present.

Diffusion from Sputum.—There is no doubt

that bacilli are diffused into the air on minute particles of sputum during coughing, and even during talking. Experiments have been made which show that even during talking bacilli may be projected as far as a meter from the patient's mouth. Such diffusion does not occur when the sputum is thick, but only when it is rather thin and free. It only takes a few minutes to cause infection of a room. The bacilli thus projected into the air on expectorated material have been found in various experiments to be still some distance from the floor at the end of from fifteen minutes to three to five hours. During rapid talking sputum is more freely projected. Certain persons seem to project much more than others. While it is assumed that inhalation tuberculosis is a thing of very frequent occurrence, it is not easy to understand how tubercle bacilli can be breathed into the depths of the lungs on dust particles or little spherules of sputum material. Jonathan Wright, of New York, the distinguished laryngologist, insists that inspiration tuberculosis is practically impossible except where people are mouth breathers. Air is carried through the moist intricate passages of the nose and then must pass the narrow apertures between the true and the false vocal cords. These moist surfaces are almost sure to entangle any foreign particles that may be present. The air in the depths of the lungs is changed not by direct currents of air that flow in and out, but by diffusion in the trachea and larger bronchi, so that it is very hard to understand how tubercle bacilli should find their way into the air vesicles. If inspiration tuberculosis were so common as it is then infection would take place mainly at the bases of the lungs, since most of the tuberculous material would find its way downwards by means of gravity. Once dust particles get beyond the trachea, if they become entangled in mucus they are certainly not likely to find their way upward against the force of gravity into the apices of the lungs, where initial lesions of the pulmonary tuberculosis are most common, but would be almost sure to find their way downward at least as frequently, which is not the case in practice.

Method of Infection.—Dr. Rowland G. Freeman said that the method of infection in tuberculosis is, of course, extremely important. Considering how much study has been devoted to the disease, it might be thought that this problem would now be definitely settled. Professor Koch, however, considers that infection through the intestinal wall is very infrequent. Professor von Behring, on the other hand, considers that infection, even through a healthy intestinal wall, is not only possible, but the most frequent method. When two such great authorities differ, the question is evidently open for discussion. The bronchial glands are so often affected as to show the frequency with which infection must take place through inhalation. Whether infection may take place through food, or not, there is a diversity of opinion. In New York it is considered to happen very rarely. In Europe, both in England and on the Continent, a very different opinion prevails. Guthrie found over 22 per cent. of infections through the intestinal tract. Still reported over 23 per cent. Heller, of Kiel, reported nearly 40 per cent. of primary intestinal affections. This seems to be the prevailing German opinion. Conheim and Aufrecht consider that infection through the intestines is by no means rare, but rather frequent. Dr. Sims Woodhead has recently stated that the mesenteric glands are nearly always infected.

Intestinal Permeability.—It would seem from recent observations that in animals, at least, infection through the intestinal walls may take place in such a way as to give the principal lesions in the lungs. Lung lesions that occur as the result of infection through the intestinal tract need not necessarily come from food. It may be the result of the swallowing of dust. Von Behring has shown that at least in young animals tubercle bacilli may pass through an uninjured intestinal membrane, producing lesions in the intestinal glands, or even at some distance from the intestinal tract. When there is generalized tuberculosis, the seat of infection seems nearly always to be the intestines.

Tuberculosis and Emaciation.—The nutrition of children suffering from tuberculosis is usually not very seriously disturbed. Emaciation always speaks against tuberculosis in young children, and rather for intestinal disturbances of other kinds. Very often the occurrence of tuberculous meningitis is in children in whom nutrition is excellent. Tuberculosis acquired very young in life may become incapsulated and later take on renewed infectious qualities. This not uncommonly happens after some other infections, as for instance measles, especially measles complicated by bronchopneumonia or whooping-cough or grip. This form of reinfection may even cause a generalization of tuberculosis or may set up a fatal tuberculous meningitis. Infection of the cervical lymph nodes, or of the joints seldom occurs under three years of age. These infections of course must take place as a rule through the circulation, so that it would seem that the entrance of tubercle bacilli into the circulation is rare in the early years of life. Abdominal infections with tuberculosis occur most commonly during the period when cow's milk is an almost exclusive article of diet, and would seem to indicate that bovine tuberculosis is pathogenic also for man. Whatever may be the port of entry of the tubercle bacillus, the bronchial glands and the lungs soon become involved.

Bovine and Human Tuberculosis.—Dr. Maczyk Ravenel, of Philadelphia, discussed the relationship between human and bovine tuberculosis. He said that if this discussion had taken place shortly after Koch's announcement of the absolute diversity of human and bovine tuberculosis, he could only have asserted his belief of the contrary and confirmed it by citations from literature. Now, however, as the result of observation made since Koch's announcement, he is definitely sure that there is not the immunity of human beings to bovine tuberculosis that Koch claims. Koch's principal argument is that bovine tubercle bacilli are always extremely virulent to animals, while human bacilli are not so virulent. It has been shown in Germany, however, that true bovine bacilli may possess but slight virulence. Dr. Ravenel himself has succeeded in isolating bacilli from human beings, that had all the characteristics of human bacilli with their special virulence, in certain cases, though lacking it in others. It has been found that bacilli, especially if existing in fat droplets, may readily pass through the intestinal wall even though the mucous membrane is uninjured. Dr. Ravenel's observations in this matter were made upon dogs. The animals were first purged by means of castor oil, so as to leave no foreign material in the intestines. Then, after being allowed to fast for twelve hours, they were fed with butter, into which had been introduced tubercle bacilli from cattle. Four hours after their meal they were killed. In eight out of ten such cases, bacilli were found to have passed through the intestinal walls. These bacilli, when injected into guinea-pigs, killed them in a comparatively short time. This was evidence that a large number of the bacilli must have passed through since ordinarily the length of time necessary to kill an animal depends upon the number of bacilli that are originally injected. In these cases bacilli were found in the thoracic duct and in the lungs, and the observations proved that though the infection takes

place through the intestine, it may show itself very markedly in the lungs.

Other Points of Entry.—The tonsils are undoubtedly sometimes a port of entry for tubercle bacilli, and these may be derived from the food. Friedmann found that in tuberculous subjects the tonsils are infected quite commonly, if careful investigation of this subject is made at autopsy, and that many removed tonsils show the existence of foci of tuberculosis. These that are derived from the food may not infrequently be bovine tubercle bacilli and show the characteristic features of this germ. Where infections of the mesenteric glands alone were found in Dr. Ravenel's own experience, two out of five of the cases showed the presence of bacilli having such decided virulence that it could only be concluded that they were genuine bovine bacilli. De Schweinitz showed this same thing to be true in two out of four cases under his observation. Theobald Smith found this special virulence to be present in one out of five cases. Schmitt, in Germany, has recently reported his observations on 16 cases of mesenteric tuberculosis, in four of which the bacilli present seemed to be of bovine origin. It is even possible that affections of the bronchial glands may be due to bovine tubercle bacilli carried into the lungs after having been emptied first into the veins from the thoracic duct.

Danger of Bovine Tuberculosis.—Dr. Ravenel does not attempt to say how many cases of tuberculosis in children are due to bovine tubercle bacilli, but of their pathogeneity for man there can now be no doubt. Bovine bacilli occur not only in the milk of cows suffering from tuberculosis of the udder, but also in such as have tuberculous affections in other parts of the body. Ravenel himself has recently found that if the milk of five cows were mixed, one of them having been proven tuberculous, though not to a marked degree by the tuberculin test, such milk when injected into guinea-pigs gave 15 per cent. of positive results. This has been confirmed by German observers. From bovine tuberculosis then the human infections constitute not a small number, and children should be guarded against the use of such products.

Heredity and House Infection.—Dr. Biggs discussed the subject of susceptibility and heredity, and said that as tuberculosis usually occurs it is a question rather of house infection than of direct inheritance. It is possible that a specific susceptibility to the disease may be inherited. In a tuberculous family, however, a child is exposed to infection almost from the first moment of its existence. It is kissed and fondled by the members of the family and may be infected with the disease and sometimes even a tuberculous mother will pass some of the food from her own mouth into that of the child. The cooling of milk foods in this way is not uncommon. Later, when the child begins to creep its hands become soiled with expectorations on the floor and it gathers up the dust which frequently contains tuberculous germs. Besides this, owing to its position so close to the floor, it breathes in the dust that is raised up by every movement through the room, and thus is likely to inhale the germs of tuberculosis.

Infection and Latent Tendency.—If the child becomes infected it may later recover, the lesion being incapsulated. Whenever, later on in life, however, there is any running down in health, this incapsulated focus of tuberculosis may become active again. This may constitute the hereditary tendency that to some minds is supposed to exist so clearly, and modern research seems to point in this way. The most important thing for the decrease of tuberculosis is the protection of children in every way and the lessening of the disease during the early years. Dr. Biggs then showed by statistics of the mortality from tuberculosis of New York city that there had been, in recent years, a very decided decrease from the death rate of tuberculosis under the age of fifteen years. This he considers the best feature of the crusade against tuberculosis and believes that it should be encouraged in every way. If there is to be an eradication of the disease it will come thus more surely than by any other means.

Entrance by the Lungs.—Dr. Thomas Darlington, of the New York Board of Health, opened the discussion of the papers. He considers that the entrance of bacili by the lungs must be admitted. Notwithstanding the very complete protective mechanism of the lungs, dust and fine particles of various kinds find their way deep into the air spaces of the pulmonary tissue. While acting physician to the Croton tunnel work Dr. Darlington found at autopsies of men who died during the progress of the work, that dust of various kinds from the quarrying and the explosions had found its way into the farthest portions of the lungs. On the other hand, he considers that tuberculosis may certainly develop from food materials, and especially from milk. It is not an infrequent experience for a physician to note persistent diarrhea in a patient and then have phthisis develop, especially in young patients.

Human and Bovine Tuberculosis.—Dr. Darlington has seen cows that fed on pastures over which the tuberculous patients of a sanitarium were accustomed to walk without proper precaution as to expectoration develop tuberculosis apparently as the result of the swallowing of tuberculous material with the grass. Food material may also prove a source of tuberculous infection, or through carious teeth. It is from these ports of entry especially that cervical lymph node tuberculosis is apt to develop and may prove a medium of further infection.

Care for Children.—For the restoration of adults suffering from tuberculosis to health it has been suggested that removal to sanitoria may constitute the best means. If adults are to be sent away from an infected home and poor surroundings, so much the more necessary is it that children should be treated in this way. It is wonderful how rapidly children improve, though there are many little patients who suffer so much from homesickness that any improvement is out of the question. On the other hand, mothers are loath to let sick children go. Well children they are satisfied to part with. If they stay they are sure to be a source of infection for other members of the family, since an ailing child is more kissed and fondled than even a well one. The question of homesickness has never been properly realized as a factor in mortality statistics. Dr. Darlington has seen an epidemic of measles with 36 patients, 18 of which died, because, when ill, they felt the need to see familiar faces and called for them frequently. This was true even when the children came to a country home only from an institution in the city. They were homesick for their old surroundings, for the nurses with whom they had been brought up. For the sanitarium treatment of children then it will be necessary to have the institutions in close proximity to the city in order that parents may have the opportunity to visit frequently.

Environment Not Heredity.—Dr. Northrup said that scarcely too much importance could be given to the educational value of the work that is being done by the Board of Health. Not long since a woman applied to have her husband removed from the home to the hospital, because she feared that he would be a source of infection. In spite of all her warnings

he insisted on being careless with regard to expectoration and she wanted to avoid the danger for the children particularly. It seems to be becoming clearer that it is not a question of heredity, but entirely one of infection that is at the bottom of the development of tuberculosis. Dr. Northrup once saw tubercle bacilli demonstrated in the circulation of a fetus that had been cut from its mother who was dying from tuberculosis by Cæsarean section. It seemed not impossible, however, that they might have been milked into the child's circulation owing to manipulations during the operation. It is certainly a rare curiosity for children to be born with tuberculosis and the rôle of heredity is assuming ever smaller proportions.

Intestinal and Respiratory Tuberculosis.—Dr. Northrup considers that it is rather easy to overestimate the importance of intestinal tuberculosis and to underestimate that which has its rise through the respiratory tract. In children the examination of the bronchial glands and the determination of their condition seems to be the crucial test of the mode of entrance of tubercle bacilli. In Dr. Northrup's own experience of 125 autopsies, every one showed the bronchial glands affected, apparently as the result of primary pulmonary tuberculosis. Only one showed such an involvement of the mesenteric lymph glands as pointed to an infection through the intestinal tract. With regard to experimental observation, the conditions established for purposes of experiment were so different from those of nature as to make the conclusions unusuitable. If tuberculosis material is forced into an intestine it is not surprising if it finds its way through the mucous membrane into the mesenteric glands, or even the thoracic duct without producing other manifestations. This must not, however, be considered as evidence of the passage of tubercle bacilli, through the intestinal mucous membrane.

Tuberculosis of the Cervical Lymph Nodes.—Dr. Dowd said that it is very probable that tuberculous infections take place, both through the intestinal and the respiratory tract, and that infections through the intestinal tract are more frequent than have been thought. It is interesting to realize, however, what little tendency tuberculosis has in certain forms of infection to spread beyond the original focus. Of 100 cases of tuberculosis of the cervical lymph nodes that Dr. Dowd has treated surgically only one has so far developed tuberculosis of the lungs. Other cervical lymph nodes have become infected and the infection has even spread to the other side of the neck, but the lungs have not become affected. Out of 1,000 surgical cases treated in hospital under Dr. Dowd's care, 212 were suffering from tuberculosis in some form. The overwhelming number of these cases were of bone tuberculosis. At present there is no knowledge of the source from which tuberculosis of bone originates. The infected material must, however, come through the circulation, though it is not frequent to find other lesions of tuberculosis in the same patient.

Localized Tuberculous Infection.—In ten cases under Dr. Dowd's care iliac and femoral glands were affected with tuberculous processes as the result of bacilli finding their way through the lymph passages from slow running ulcers of the feet. These ulcers started in traumata of various kinds, especially as were due to slivers of wood from old floors or portions of kindling wood and the like. Tubercle bacilli were demonstrated in all of the cases. Dr. Dowd considers it rather surprising to find that tubercle bacilli should be so common on the streets of New York that slivers of wood should be capable of bringing about an infection from this form of disease.

Possible Infection Through Mucous Membrane.—Dr. Samuel Hamill, of Philadelphia, said that recent observations have shown beyond all doubt the possibility of tuberculous infection through uninjured mucous membrane. Such a pathological event is not frequent, yet it is certain that it does occasionally occur. The other important fact brought out by recent observation is a sort of corollary of the first and shows that tuberculous lesions may be quite far removed from the original port of entry of the tubercle bacilli, and yet show very little signs of the course they have traveled in reaching the point at which they produce a lesion. Dr. Hamill said that there is no doubt now that tubercle bacilli may pass with the chyle through the intestinal wall into the lacteals, thence to the thoracic duct and finally into the superior vena cava, and from here the distance through the right heart to the lung is not far. While lesions of the thoracic duct have been found they are not frequent. Very few of those who make autopsies will be able to say definitely whether the thoracic duct was affected or not, since usually it escapes all notice, and it is only in recent years that this subject has been investigated. Lung infection from the intestines, however, without any intermediate lesions from the intestine, is not only possible, but seems actually to occur much more frequently than has been thought. With regard to general tuberculosis in infants, Dr. Hamill is of the opinion that these cases may be due to bovine tuberculosis, because of the special virulence which this form of the bacillus has for human beings and other animals.

Infection from Cattle.—Dr. John H. Girdner said that in his own observation cases of tuberculosis seem to develop for which the only source of infection that could possibly be blamed was tuberculous material from cattle. The cases occurred in a mountainous district where there was very little dust, and where for miles there were no sufferers from tuberculosis. Human infection could absolutely be excluded. The patients lived almost exclusively on dairy products and the cattle from which these came were the scrub mountain cattle, thin and scrawny, that had been inbred for many generations. The breed was degenerate and there were evidences of tuberculosis in some of them. Under such circumstances it seems very probable that there can be an actual transfer of the tuberculosis from the cattle to human beings. This may not be frequent, but it constitutes a source of danger that must constantly be guarded against and with regard to which Koch's announcement by his tendency to allay suspicion is likely to do much harm.

Intestinal Infection.—Dr. Ravenel, in closing the discussion, said, in answer to Dr. Northrup's objection that the animals in his experiments were injected directly into the bowels with large cultures of tubercle bacilli that this was never technic. In the cases that he had reported nothing contrary to the ordinary course of nature was permitted. The animals were compelled to fast for twenty-four hours, were given a purge to remove materials that might be present, and then were given a simple meal of fresh butter, which they ate with great avidity and digested rapidly; the fat droplets, however, in the course of absorption, carrying the tubercle bacilli through the intestinal walls.

Chinese Made Easy.—It may come as a surprise to many physicians, particularly of New York, that an accomplished Chinese scholar is in their midst. Fortunately Dr. Walter Brooks Brouner has tried to spread the knowledge gained by many years of hard work. We hope to soon present a review of his interesting book.

NEW YORK ACADEMY OF MEDICINE.

Section on Genito-Urinary Diseases.

Stated Meeting, held April 20, 1904.

The President, James Pedersen, M.D., in the Chair.

Anuria Due to Obstruction of Both Ureters by Calculi.—Dr. A. V. Moschcowitz presented a man, forty-eight years old, who had been admitted to Mt. Sinai Hospital November 25, 1903. Five years before he had an attack of pain in the right side of the abdomen. Since then he had been in fairly good health except for repeated attacks of lumbago. On November 16, 1903, he complained of rather severe pain in the left side of the abdomen. Six days later he voided his urine voluntarily and then did not void any for three and a half days, or eighty-four hours. When he was admitted to the hospital, November 25, his bladder was found to be empty and there was a urinous odor about the patient. In view of the fact that there had been pain upon the left side and again upon the right side some time previous a diagnosis was made of complete anuria of calculous nature. The patient was in fair condition, so that a double nephrotomy was indicated and performed. The result of the operation verified the following: There were no calculi or foreign body in either kidney; the perineal fat on the left side was edematous; the left kidney contained cloudy urine; the right kidney contained pus and urine mixed; a bougie introduced into both ureters revealed an obstruction approximately 6½ or 7 inches from the skin incision down in the ureter. The kidneys were drained and the patient placed in bed. The next day the patient felt very comfortable and both kidneys secreted urine; in fact, the patient laid in a pool of urine in the bed. December 29 the condition of the patient was such that Dr. Moschcowitz thought of going further and relieve or cure the patient completely. At that time he bent a tube at an angle and introduced it into the pelvis of the kidney; through this tube a bougie was introduced into both ureters and then there was found an obstruction on the left side about seven inches from the skin incision and, on the right side, about six inches from the skin incision. The cystoscopic examination was very interesting. The bladder contained but very little fluid and this examination was quite difficult. The right ureter was seen as was the left. This examination revealed a white roundish body which was thought to be in the mouth of the ureter and was believed to be an impacted calculus in the left ureter. The skiagraph picture was not satisfactory. In view of the fact that there was believed to be something in the mouth of the left ureter, which the doctor took to be an impacted calculus, a suprapubic incision was made on January 4, and he was very much surprised not to find any. The incision then made was utilized for the introduction of a catheter into both ureters until they met with obstructions. Immediately he made an extraperitoneal incision upon the right side of the abdomen, exposing the ureter, which was found to be enlarged and thickened. Just above the linea arcuata a large stone was found obstructing the ureter; this was extracted and the incision in the ureter sutured with catgut and the opening in the abdomen closed by layer suture after introducing a cigarette drain. There was no shock following the operation. On the day following four and a half ounces of urine were voided. Two weeks later the same procedure was performed on the opposite side, the operative steps being practically the same. That is, the ureter was exposed, incised, and in this case the obstruction was found below the linea arcuata in the form of a calculus. It was with difficulty extracted, but by gentle massage it was pushed upward and withdrawn. The patient made a complete recovery, and there was no leakage from either side. The second operation was performed on January 18, and the patient left the hospital on February 10. Both kidney incisions had healed kindly. Today he had a sinus which led down beneath the skin and no doubt will close very soon

Dr. Joseph A. Blake said that he had found a very good way of stripping the stone along the ureter into the field of incision was to take a ringed sponge forceps and stroke the stone through the ureter toward the incision. In his hands this was better than using the finger, inasmuch as the ring caught and controlled the stone even through the wall of the ureter.

Dr. F. Tilden Brown said that the distention of the pelvis gave an indication of a longer or shorter retention of calculi. He asked if it would not have hastened the operative procedure which was finally made in the abdominal region if the ureter catheter had at once been passed up each ureter until it met with the point of obstruction or lodgment of the calculi? Then, without resorting to nephrotomy, to have made an ureteric incision and there removed the calculi. But the brilliant result in this unusual and critical case leaves no room for any criticism.

Dr. Moschcowitz was under the impression that five years ago when the patient had the severe attack of pain supposed to be due to appendicitis, it was due to the downward passage of the calculus and which, at that time, blocked the ureter. To him it was a great point of interest to know how such a kidney should act if it was assumed that its ureter had been blocked for five years. It had been suggested that at no time was the ureter completely blocked, at least until the additional strain was put upon it by the blocking up of the other side. From the gross appearance of the kidney he did not expect that the kidney would take up its function, although it apparently had. With regard to doing a ureterocystotomy at the primary operation he could not say that this would have been the better course to pursue. What then was needed was to relieve the kidney of its distention so that the kidney could functionate again. He said it was almost impossible to make an absolute diagnosis of calculus anuria, but were it possible it is best to meet primarily the vital indication, which in these cases is only a nephrotomy.

Repair for Large Defect of Urethra.—Dr. A. V. Moschcowitz also presented this patient. He had never had lues or gonorrhea. He was admitted to Mt. Sinai Hospital last spring when he gave the following history: About one year before his admission to the hospital he had a painful swelling in the perineum which was thought to be an abscess and was incised at some hospital in New York. Since then there had been dribbling of urine. One day before admission he was cystoscoped by a physician and sent into the hospital with a diagnosis of tumor of the bladder. He would have come anyway because shortly after he had a severe chill and rise of temperature. Upon admission to the hospital there was found an extensive phlegmon of the perineum and scrotum and a fistula which led to some part of the urinary tract. This abscess was incised in different directions, and, in spite of the septic condition, the patient made a good recovery, but the fistula remained. The patient was discharged, but readmitted September 14. Two days later the fistula was laid bare. From the previous abscess and the gangrenous loss of urethra there was found a defect which extended nearly to the rectum, 3½ inches in length. After the parts had been thoroughly cleansed the question arose how to repair this extensive defect. The epithelium had gradually grown toward the urethra on both sides; therefore

he dissected it up for three-quarters of an inch on either side, introduced a catheter through the urethra into the bladder, and united the cutaneous flaps over this catheter, uniting them in the median line. The catheter was left in for two weeks and then the wound was practically healed. The endoscope now showed a peculiar condition of affairs, as the urethra does not collapse at the end of the tube, but remains patulous for some distance beyond it. It was possible to pass a 30 Fr. sound with ease and comfort. The patient retains his urine well. The man is more or less morose because he has lost his power of copulation, which he believed was due to the extensive loss of muscle of the perineum and,

in a greater measure, to the division of the nerves which supply those various muscles.

Presentation of Some Cystoscopes Designed for Different Purposes.—Dr. F. Tilden Brown exhibited these. He said he would esteem it a privilege to show these instruments before this particular section of the Academy of Medicine, and to hear the criticism of those who have used any of them. So far as he has been able to ascertain, his original double-barrelled ureter cystoscope, Fig. 1, B, was the first instrument of any kind which in both sexes catheterized the two ureters synchronously. This was but a modification of Brenner's single catheter cystoscope, Fig. 1, A, and in-

Fig. 2.

DR. F. TILDEN BROWN'S DOUBLE CATHETER AND TWO-WAY IRRIGATING CYSTOSCOPE.

volved no new principle in construction or of technic. In former publications[1] he has explained the nature of the limitations of the two instruments just referred to, as well as wherein requirements for something better led him, aided by Mr. Rheinholt Wappler, to gradually evolve and by continued clinical tests to perfect his present type of cystoscope, the aim of which was to assemble two irrigating channels, two catheter canals and a telescope all in a circumference of 24 Fr. The basic feature which made this feasible was a lamp-tipped open sheath needing an obturator to pass it to the bladder, then the obturator was replaced by a telescopic tube, carrying two catheter canals. Thus by omission of the old time terminal window the essential space was gained, and a departure made from the antecedent types of cystoscopes. The change provided for several different ways of rapid bladder irrigation or change of distending medium, whether water or air. It also obviated the risk rather remotely inherent to other catheter cystoscopes of having the catheters or catheter canals catch up infectious material while passing through the urethra. This scheme as first developed in the catheterizing instrument, Fig. 2, was found to be practicable, and it was but a natural amplification of it to equip the same sheath with other interchangeable telescopic tubes having supplementary purposes, this set making up what was called the composite cystoscope, Fig. 3. As first made the telescopic tubes reached only to the convexity of the sheath and tip, it was later learned that the visual properties were greatly improved by having the telescopic tubes protrude into the bladder, so as to bring the terminal lens on a vertical plane not much behind that of the lamp, as shown in Fig. 4, when on account of this proximity of lens and lamp a brighter illumination was had than with previous forms of cystoscopes. When the catheterizing telescope is in use the matter of illumination is of particular moment because on the trigonum the mucous membrane is most apt to be congested and dark. In this region the projecting prow of the instrument serves an additional purpose, that of

Fig. 3.

DR. F. TILDEN BROWN'S COMPOSITE CYSTOSCOPE.

depressing a slight ridge of mucous membrane, which in some bladders tends more or less to intercept the horizon between the internal meatus and the ureter mouths. In addition to the advantages mentioned in having the terminal lens extended forward, it is just as important to have the underlying catheter canals terminate almost on a line with the lens, for two reasons: (1) That these canals may give sufficient support to the flexible catheters in order to overcome a muscular resistance occasionally met with at the ureter mouths or a trifle within; (2) that the catheter points when advanced may have no chance of plowing over this sensitive part of the bladder.

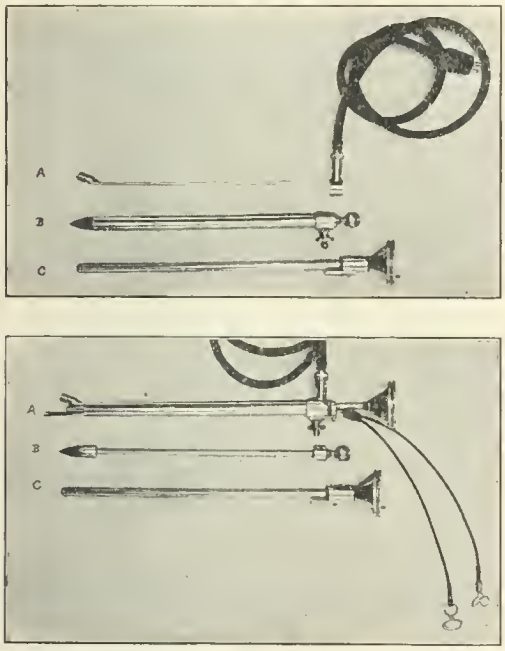
Dr. Follen Cabot said that, in his experience, the oval sheath was easier to introduce than the cylindrical one. Upon withdrawing the instrument the catheters could be left in place. He had held the catheters in place as long as fifteen minutes without getting much urine. Withdrawing the instrument in this way and leaving the catheters in would enable one to wait for hours, if need be, to get sufficient urine for examination purposes. The instrument he referred to was made without separate chambers for the catheters and had been used in over a hundred cases with perfect satisfaction. This ureter cystoscope could also be used for observation. It had been devised by the speaker somewhat along the lines of the Brenner and F. Tilden Brown instruments, and will be shown at the next meeting of the Academy (Genito-Urinary Section).

Dr. George K. Swinburne said that a point of advantage in Dr. Brown's instrument was that the instrument

[1] Annals of Surgery, Vol. XXX, p. 661; Annals of Surgery, Vol. XXXV, p. 642; Medical and Surgical Report of the Presbyterian Hospital, Vol. V, p. 670.

could be passed into the bladder and the bladder washed out through the tube and then the telescope inserted without withdrawing the instrument. This was an advantage possessed by no other instrument. Oftentimes the fluid within the bladder would become so muddy that one could not see and the possibility of washing out the bladder without withdrawing the instrument made it of additional value. One often could see something when the telescope was introduced which a moment later would not be apparent. Dr. Brown spoke of withdrawing the instrument into the neck of the bladder before inserting the telescope. He said he had been in the habit of simply raising the proximal ends so that the opening was on the bladder floor; thus the bladder contents were retained. He had noticed that when the opening got into the bladder neck, pushing it forward sometimes scraped the neck of the bladder and caused enough bleeding to make the cystoscopic examination

Fig. 4.



DR. F. TILDEN BROWN'S SUPRAPUBIC TROCAR CYSTOSCOPE. (Used with the same telescopes as in Fig. 3.)

impossible. The lenses in the Nitze cystoscope he considered to be clearer, but so far as the practical working of cystoscope was concerned Dr. Brown's instrument he believed to be superior to the Nitze.

Dr. Follen Cabot said the irrigation attachment could be used for filling the bladder. After the telescope was secured in place it could be filled through this irrigating attachment, running the fluid in one side and out through the other. He said that if the catheters were to be left in place and the instrument withdrawn they should be pushed in farther than usual. He had found that the catheters, unless very small in size, were likely to catch in an attempt to withdraw the Brown instrument, whereas with his cystoscope this difficulty had been overcome by the omission of the separate catheter compartments and other changes in the instrument.

Dr. F. Tilden Brown thanked Dr. Swinburne for his allusion to the points mentioned regarding the proper place on the trigonum for resting the open sheath to promote escape of the distending medium during interchange of the telescopic tubes, although, as Dr. Cabot had stated, it was a feature of the instrument that such irrigation could be carried on with the telescopes in the sheath. Dr. Brown said that if there was any particular reason for keeping a catheter in the ureter for some length of time it was of course better to employ a long catheter and pass it nearly or quite to the renal pelvis, but he showed how easy it was to manage the withdrawal of the cystoscope so as to leave some short catheters in the ureters. For a number of reasons he was opposed to the plan of leaving a catheter in the ureter, as well as to the withdrawal of the cystoscope until the urine collection had been completed. It was in order to obviate this necessity which had led him to provide the extra inlet and exit channels so that the vesical distention could be relieved as soon as the catheters were in the ureters. The to and fro motion of the tip of a catheter in the ureter, which must take place more or less during removal of the cystoscope, was very apt to cause an exfoliation of the ureteric epithelium and some admixture of blood with the collected urine. It seemed scarcely necessary to point out the errors which might thus accrue from the presence of blood in one or both of the urine specimens when it did not properly belong there.

Dr. H. W. Van Allen, of Springfield, Mass., opened the discussion by stating that there seemed to be two classes of men present, viz., the gentlemen who were surgeons and who cared but little about the high or low vacuum tubes, but who looked upon them as a means of accurate diagnosis, and the gentlemen who were doing X-ray work for the surgeons. In speaking of renal calculi he said there were no symptoms that were constant and even one of the more recent text-books, in referring to kidney stone, stated "pus in the urine was the only constant symptom of kidney stone," while on the same page it was stated "pus from the kidney is not a constant sign." This to him showed that aid was required to more accurately diagnose this condition. He said that Dr. Cole alluded to the ray of selective absorption. It was this quality of light and not the quantity which gave the details necessary for accurate diagnosis, and there should be unison between the interruptor, the tube and the coil, and he believed that it was in this unison that Dr. Cole had so well succeeded in his work. Dr. Van Allen had tried to get this ray of selective absorption and said it was very easy to talk about it but harder to get, and he related a case in point. A man gave all the clinical symptoms of renal stone but the ray did not show any, although there was detailed bone, etc. It was only on the third attempt that any stone was demonstrated. The use of an absolutely dark room he believed to be very essential for this kind of work, allowing only a little weak ruby light at times. He used a weak but long development and so did not lose many of the details. He had been using intensifying solutions with success, for it brought out additional details on the plate. He related an instance of a patient with stone in the bladder and the plate was not at all satisfactory, three stones showing faintly. When the intensifying solution was used four stones were plainly shown and later the man presented himself with the four stones he had since passed. He believed older tubes gave better work because of some change in its structure making it capable of better regulation.

Dr. Robert Abbe continued the discussion and said that it had been his experience to always find the stone by radiograph if present, even when so small a one as but eight grains of uric acid; in that instance the stone showed most beautifully with a tube of ordinary vacuum. He had come to the conclusion that any tube that would

give a good bone picture would give a good stone picture, and this conclusion was justified in the instance referred to where an eight-grain uric acid stone was beautifully shown on the plate, which also showed well the transverse processes of the vertebræ. If one could represent the transverse processes on the plate he felt sure that any stone would be shown if present. His belief is that the differentiation of the varying density of soft tissues is a distinct advance in skiagraphy, but that, in the search for calculous material it seems unwise to elicit any differentiation of structures other than bone and calculus. There is not any structure in the body at all resembling in density either bone or stone which by their both containing earthy salts are much alike in density, hence whatever selective ray will take a bone picture will take a stone picture.

He said that this was a subject that appealed very greatly to him, coming as it did to the surgeon's aid within the last five or six years, for he now could prove the presence of renal stones which before were only suspected. He recalled one case that for a year was treated for sciatica, for he presented few urinary symptoms. Microscopical examination of the urine had been made once and only a few blood corpuscles found. The picture taken showed very beautifully a stone in the upper part of his right kidney weighing 15 grains.

A matter of much interest to the surgeon, when he has a skiagraph showing renal calculus, is the fact that in a majority of cases the stone is not in the pelvis of the kidney, but has a separate cavity in the kidney substance from which it often is extracted with difficulty. It has first grown from a crystal formed in a uriniferous tubule at the summit of a pyramid. This grows larger at the expense of the pyramid, until an excavation is created as large as the stone, one corner of which peeps out into the pelvis. When the operator introduces his finger into the renal pelvis he is surprised to find no stone, but a metal probe soon detects a grating which he finds and loses several times—then slips the probe into the calculus pocket, passes a bistourie alongside, slits up the small opening and extracts the stone. One further note is worth recording: That several pyelonephrosis cases have made permanent recoveries, after removal of the large stones, without removal of the kidney.

Dr. F. Tilden Brown said that Dr. Cole's masterly exposition of fine X-ray work, which he explains as due to a perfect adjustment of tube, coil and interrupter so as to yield rays of selective absorption, has been most interesting and instructive. The differentiation of tissue shown in many of his plates by reason of this quality of the rays brings out such a variety of detail, especially the high and low lights resulting from gas and fecal masses in the intestine, that it would not be an easy matter for any except an expert to interpret the whole. It is daily becoming more evident that this branch of medical science can only expect full justice from those who make it a special study. A year ago in the discussion of this same topic he said regarding the value of X-rays in the diagnosis of renal calculus that the method was not authoritative when the radiographic returns are negative, but that it was authoritative when affirmative; that is, where two or more plates, differentiating the normal structures clearly, showed identical abnormal shadows in the region known to be occupied by the kidney which had given the ordinary clinical symptoms of stone. Considerable experience had not diminished this confidence until the advent of a recent patient, in the person of a young Cuban woman, who came to him for operation through the courtesy of Dr. Henna. Before reciting the details he would like to propose that the two excellent radiographic plates made in Dr. Townsend's studio of this case be submitted now to any one or several of the experts present for interpretation as to whether the shadow represents a stone or not. Now that Dr. Cole reports that this shadow might reasonably be expected to indicate the presence of a stone he would say that, although Dr. Henna had wisely suggested that Dr. Brown should do ureteral catheterization before operating, but he advised against it as unnecessary, in the face of a distinct shadow in two X-ray plates backed by a typical calculous history, being actuated besides in this advice by the fact that several careful microscopical examinations of the urine for tubercle bacilli had been negative. During right lumbar nephrotomy they found the fatty capsule irregularly cicatricial and adherent, on exposing the renal cortex a hickory-nut-sized hard mass was felt in the parenchyma beneath the convex border a little below its center; this was cut down upon, but instead of uncovering a stone it proved to be very condensed tissue. A moderately dilated pelvis was then explored by the finger, and from within this cavity the finger tip was worked into several of the calices. The same finger within the kidney, aided sometimes by the thumb of the same hand or by the forefinger of the opposite hand without, made a searching palpation of the entire organ and the upper two inches of the ureter; in this way several hard spots were felt in the parenchyma, but they were all much smaller than the original one, and although presumably of the same nature each was nevertheless subjected to blunt needling. At the end of this examination they were satisfied that there was no stone in the kidney, nor did the finger or the various metal instruments detect the presence of any fine calcareous matter in these indurated nodules. Palpation of the ureter showed it to be about normal size and far too small to have permitted the recent passage of a calculus corresponding to the X-ray shadow. For three days the bladder urine was much blood-stained. The patient had no unfavorable reaction and the parietal wound was closed on the third day. After convalescence cystoscopy in conjunction with synchronous ureter catheterization revealed a moderately ulcerated right ureter mouth, presenting the typical features of a very chronic tuberculosis, and although additional search has been made for tubercle bacilli in the separate urines without success, we have little doubt but that the X-ray shadow was produced by a condensation of tissue in the right kidney, probably caused by a rather unusual tuberculous process. The fact that this kidney was firmly fixed by a cicatricial state of much of its capsule makes it easier to comprehend how a good X-ray plate could bring out differentiation in the kidney tissue in a way it could not have done if the organ was making the normal excursions incidental to respiration. Dr. Brown feels that in the future cystoscopy and ureter catheterization are to be given greater importance in the corroborative diagnosis of all cases where even affirmative evidence of renal or ureteral calculus has already been had from X-ray and clinical examination. Had he made the ureter catheterization test in the case cited before the operation and learned from it that the left kidney was healthy and the right diseased, he would have been in a position at the time of the fruitless nephrotomy for stone to have done a nephrectomy instead of having probably to subject the patient to this additional operation in the future.

Dr. Willy Meyer said that it seemed to him better to have an X-ray picture taken for diagnosis of renal calculi than to attempt a uretero catheterization. This opinion held good for males as well as for females. He asked the opinion of the reader of the paper regarding

the advisability of blowing up the colon with air, as advocated by some European authority; by so doing it was claimed that the shadows were much better portrayed. Dr. Meyer related the history of a lady, thirty-two years old, who gave a history of calculus in the left ureter. She had a high temperature and presented symptoms of an acute pyelonephritis on the left side, and it was thought best to wait until her symptoms improved before taking an X-ray photograph. The patient got better. On the day set for taking the radiograph she suddenly developed chill and high fever and it was thought best to operate at once. A kidney with a large pelvis was found, brownish-red in color, extremely brittle and, within the cortex, there were found many abscesses.

A smear was then taken and culture test made and the kidney was then split, but no stone could be found, compression being made on the renal vessels. A bougie was passed into the ureter and low down was found an obstruction. A catheter, with an open end at the tip, was introduced and the ureter was flushed with water and the water returned. Whether it was a stone or a stricture that caused the obstruction was not then known. No cystoscopic examination had been made and he did not even know whether there was a kidney on the opposite side. The kidney was drained, the patient improved, but the kidney wound refused to heal. Palpation through the vagina did not reveal any hard mass in the pelvis.

He then catheterized the ureters, using the Kelly method, and it was interesting to him to find an obstruction which he could pass; when passed there followed a gush of about one ounce of urine. The ureter and renal pelvis were irrigated with a sterilized boric acid solution. On pulling back the tip of the instrument to the place of the obstruction he found the water stopped and then again began to flow on further pulling out the catheter, which led him to believe he was dealing with a small pouch in the ureter, probably containing a stone. A waxed-tip catheter, which was introduced afterward, showed a mark. After the patient had improved, an X-ray picture was taken and two stones were shown in the pelvic part of the ureter. The smaller one was passed. The patient was operated upon, an abdominal incision made, and just at the place where the uterine artery crosses the ureter was found the larger calculus. This patient then made a good recovery. Within the last year Dr. Meyer had seen two patients with renal calculi. One was a patient of his own who had an attack of acute retention ushered in by renal colic. A diagnosis of renal calculus was made. The patient also had an enlarged prostate, which was removed by the perineal route. He was about to go West when he was suddenly seized, while riding, with a chill, high fever, prostration and symptoms pointing to renal colic or an attack of appendicitis. Within the next twelve hours he had another chill, high fever and symptoms of sepsis of a most acute character. He was operated upon and in the mucosa of the pelvis of the kidney was found a distinct spot of necrosis where a stone had rested for some time and caused a pressure necrosis. A pure culture of the colon bacillus was made. The other patient, had about the same history, was profoundly septic and died six hours after Dr. Meyer saw him. Dr. Meyer mentioned these cases because some thought that the treatment of renal calculi was on the border line of medicine and surgery. He always advised patients suffering from renal calculi to submit to operation, if previous colics were accompanied with septic symptoms.

Dr. Carl Beck said that having succeeded in obtaining an indistinct shadow in renal tuberculosis which was caused by calcareous deposits in the foci, he tried to determine experimentally to what extent destructive processes in the kidneys could be represented by the Roentgen rays. The result was that a moderate amount of calcareous matter could be recognized by the use of the diaphragm as a light and disseminated shadow in contrast to nephrolithiasis, which cast a darker and more confluent shadow. When no calcareous deposits existed in association with the tuberculous process, skiagraphic representation with our present means seemed to him to be unreliable. In one case a large tuberculous cavity showed at the upper and a smaller one at the lower pole of the kidney which had been bisected. In another skiagraph demonstration was demonstrated the proportional degree of translucency which was naturally more marked at the upper pole. This translucency, however, did not show distinctly if skiagraphed through the abdominal wall, so that it could not be relied on practically. In exploratory nephrotomy, however, this translucency could be ascertained by a fluoroscope surrounded by sterile gauze, so that the foci might be located before the renal tissues were divided.

Dr. Sinclair Tousey said that the radiographs shown by Dr. Cole were excellent and represented an amount of study as to technic which only those of us could realize who have tried to obtain the same results. For large or corpulent patients he had used a board such as was shown for compressing the abdomen. It effected a reduction of two to three inches in the thickness of the abdomen and did not cast the slightest shadow on the plate, and enabled him to extend this method of examination to patients too large to be sure of results in the ordinary way. Very lately a compression cylinder had come into use in Germany, and the picture which he presented, from the *Journal of Physiologic Therapeutics,* illustrated its use. A cylinder, five inches or so in diameter, was placed on end upon the abdomen and the light from the X-ray tube shown down the cylinder. The pressure of the cylinder compresses the abdomen and reduced the thickness of tissue to be penetrated, and the lead pined walls of the cylinder presented all but the direct rays from the anodal disk from reaching the plate. Cutting off all the diffuse light arising from the walls of the X-ray tube was claimed to produce a much clearer picture. The size of the picture, however, was only about five inches in diameter. He said an X-ray picture was not like an ordinary photograph produced by focusing rays upon given points, nor was it like an ordinary shadow. It was really a chart of the relative density of the parts presented upon the plate. For instance, upon a certain part of the plate was cast the shadow of a column eight inches inheight and of the density of water and, on another part of the plate, the shadow of a similar column to which a pinch of bone salts had been added. The difference in relative densities, of course, was so slight that it took perfect technic to show it all. He showed, therewith, his radiometer in which by the number of thicknesses of the tin-foil rendered transparent he could determine the degree of vacuum in the tube. He found a mathematical standard like this of the very greatest value in this delicate work. The proper degree of vacuum for renal work would produce a picture of the kind shown in which the flesh and nails were visible, the bones almost black and the internal structure of the bone showing. It represented about No. 3 on his radiometer scale. The radiographs of the pelvis and lumbar region which he had brought for exhibition showed about the right amount of penetration for diagnostic work in the case of suspected renal or ureteral or vesical calculi, the detail shown justifying him in this opinion.

BOOK REVIEWS.

Diseases of the Intestines and Peritoneum. By Dr. Hermann Nothnagel, of Vienna. The entire volume edited, with additions, by Humphrey D. Rolleston, M.D., F.R.C.P., Physician to St. George's Hospital, London, England. W. B. Saunders & Company, Philadelphia, New York, London.

The present volume of the Nothnagel series is noteworthy as the contribution of this great German series of text-books on medicine of the distinguished editor himself, Professor Hermann Nothnagel, of Vienna. The original volume in German was one of the earliest of the series and was issued some ten years ago, but this English translation is from the second edition which came from the press only last year. A number of additions have been made by the English editor, among them especially sections on Intestinal Sand, Sprue, Ulcerative Colitis and Idiopathic Dilatation of the Colon. The section on Intussusception of the Colon has been greatly enlarged by the contributions of Dr D'Arcy Power, the distinguished authority.

In general it may be said that no text-book in English on this subject is nearly so complete as the present volume. Practically every page bears evidence of additions from the English editor's hands. The references to recent English and American literature are especially complete. On one page we note no fewer than six references to American articles, none of which were published prior to 1901. There is perhaps even a tendency to quote too many opinions that are not as yet quite firmly fixed or generally admitted as genuine contributions to medical knowledge, opinions that will require more time and further confirmation or limitation before their true significance can be realized.

With the original material compiled by a German medical clinician and the editorial work done by an English physician it might be thought perhaps that the subject of appendicitis would not receive as full treatment as it is considered by Americans to deserve. This will not be found to be the case, however. The discussion of the subject is especially complete. The conservative attitude of the original somewhat modified by the English editor makes indeed as thoroughly practical a discussion of appendicitis without sensational features as could be desired. The volume is a welcome addition.

The Therapeutics of Mineral Springs and Climates. By I. Burney Yeo, M.D., F.R.C.P. W. T. Keener & Co., Chicago.

Now that natural therapeutic measures are attracting much more attention than formerly, such books as Dr. Burney Yeo's, with regard to the therapeutic possibilities of the different mineral waters as well as the régime which is practised at the springs and their varying climate environment, cannot fail to be of special interest. For those who are likely to have patients to send to any of the various watering places or health resorts of Europe or North Africa this book will prove an excellent guide. No place of any importance is omitted, and definite information of the kind likely to be looked for by a physician is given with regard to each of them. We have, of course, in this country a variety of climate and of mineral water amply sufficient for this form of therapeutics, but there are those who feel the necessity for something more distant to effect a cure in their cases, and for patients who need the all-prevailing influence of such a suggestion the physician who has not himself had opportunities for wide European travel will, with the aid of this book, be able to pick out the locality likely to be of service.

Clinical Treatises on the Pathology and Therapy of Disorders of Metaboliam and Nutrition. By Dr. Carl von Noorden, Physician in Chief to the City Hospital, Frankfort a. M., Part V, Concerning the effects of Saline Waters (Kissingen, Homburg) on Metabolism. E. B. Treat & Co., New York.

This series has a very definite practical clinical value that can scarcely fail to commend it to those who are looking for rational therapy for the commoner forms of disease. This number of the series is at least as interesting as others. The variations of opinion as to the effect of salines on the system from the merely mechanical withdrawal of serum, the only action according to some, to the most striking alterative effects as claimed by others, are discussed from the practical standpoint of case histories. Salines have been found useful, especially in superacidity of the stomach, though nervous superacidity is not always relieved. They do good occasionally, however, in anacidity, also. On the other hand in spite of the warning at Carlsbad and many other saline springs that persons taking the cure must not eat fat, salines have been found not to hinder but rather to help the digestion of fat.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared original Articles, on Treatment, Medicine, Surgery, etc., by leading members of the Medical Profession Throughout the World. Volume II, Fourteenth Series. J. B. Lippincott Co., Philadelphia.

The present number of the International Clinics contains an especially informing set of articles on the diseases of warm climates. Among them the article by Dr. Mason, U.S.A., on the "Spread of Diseases by Insects, with Suggestions Regarding Prophylaxis," will be found eminently useful outside the tropics also. The series also contains articles on "Malarial Hemoglobinuria" and on the "Etiology of Bilious Hemoglobinuric Fever," that will be of special interest in our Southern States. The last article of the series on the "Treatment and Mode of Life to be Pursued on Return to a Cold Climate by Those Suffering from the Commoner Affections Incidental to a Sojourn in Tropical Countries" should be read with attention by physicians all over the country, since very few medical practitioners of wide experience fail to have among their patients returned soldiers from the Philippines and other American citizens who have come back, with or without the fortune they went to seek, from Cuba, Porto Rico and our other more or less tropical possessions. The rest of the volume is taken up with the clinical lessons quite up to the usual high standard.

Burdett's Hospital and Charities, 1904, Being the Year Book of Philanthropy and the Hospital Annual. By Sir Henry Burdett, K.C.B. Scientific Press, Limited, London.

Sir Henry Burdett's Manual of Hospitals and Charities is too well known to need anything more than a notice of the present yearly issue. Most of the book of course is devoted to hospitals and other charitable institutions in the British Islands. There is, however, some sixty pages devoted to hospitals in the United States of America, and under the head of Colonial Hospitals, some fifteen pages devoted to Canada. The book will accordingly have more than an academic interest for Americans and at the same time serving as an exhaustive guide and directory for the English medical charitable institutions. Naturally the edition is distinctly defective for American hospitals, some of the most noted being omitted.

THE MEDICAL NEWS.

TECHNICAL ERRORS IN THE USE OF RUBBER GLOVES.[1]

BY HOWARD D. COLLINS, M.D.

OF NEW YORK;

ASSISTANT SURGEON, CITY HOSPITAL; ASSISTANT DEMONSTRATOR, COLUMBIA UNIVERSITY.

ABOUT five or six years ago the question of the use of some form of glove to be employed in operative manipulations was revived. While not a new proposition, the discussions aroused at that time were listened to with much interest by American surgeons and particularly by those in New York. As is always the case in the problems of the medical profession, there were numerous arguments advanced by the opposing factions, although the great majority recognized the immense superiority of the glove over the naked hand from the standpoint of asepsis. There was, though, much division of opinion as to the kind of glove to be worn, the method of use and whether or no the surgeon's skill was handicapped.

It would not be of value to review these arguments now, but it is of interest to note that eight years ago there were but very few operators in this country who made any attempt whatever to wear gloves as a routine during operations. At that time the practical use of gloves was limited to occasional instances as a self-protection when operating on highly infectious cases. Now, on the other hand, the majority of surgeons look upon the use of gloves as much a matter of course as any of the rest of our aseptic technics.

The consensus of opinion is also in favor of a glove made of pure impervious India rubber and a gum glove is the kind almost universally adopted.

The writer does not wish to reiterate the arguments advocating the use of rubber gloves, for he assumes their value is taken for granted and proven. He wishes, however, to point out the technical errors in the use of rubber gloves, because it is possible to witness many surgical operations where several people are employed and see gross errors of technic in the manner of using gloves; errors not so much of carelessness, but of lack of instruction and thought on the subject. This applies particularly to the internes on our hospital staffs and nurses. We assume that the surgeons-in-chief have studied the subject and errors on their part we ascribe to carelessness, but the juniors are receiving their training and the details of instruction should not be neglected. Their thought and power of logic should be waked so that a correct routine becomes a matter of almost unconscious habit. To more thoroughly eradicate the errors, it would be wise to rehearse the purposes the gloves serve in advancing the cause of asepsis.

Foremost it is impossible to assume, beyond all question, that one can by the use of antiseptics prepare the hands of all persons employed in an operation, so as to be confident that each and every hand is sterile for each operation. Of course, many times some of the hands are aseptic, but one cannot be sure that all are invariably so.

Gloves of pure rubber can be unfailingly rendered aseptic by boiling. Another point of greatest value is that impervious gloves preclude the possibility of exfoliations and detritus, from the hands, entering the surgical wound. A third point is that a smooth surface like a rubber glove can be more readily freed of coagulated blood and other materials than can the rough skin of the hand. The first argument in favor of the use of gloves is the one which the writer believes is most frequently set at naught by the careless manner in which the gloves are drawn on the hand. For example, the surgeon washes his hands in the most thorough manner, rinses them in various powerful antiseptics, according to his fancy, dries his hands on a sterile towel and is now ready for his gloves. Are his hands sterile? Does he know it for a fact? If so, he is foolish to go to the trouble of wearing gloves. On the other hand, does he doubt the asepsis of his hands? Is he credulous? If so, note how he vitiates his technic by his manner of putting on the gloves. Over and over again, by those who should know better, I have seen it done as follows: The gauntlet or wristband of the left glove is seized in a generous grasp by the right hand, and the left hand pushed into the gloves as far as possible; then with the naked right hand the finger tips of the left glove are stroked into place and the glove nicely adjusted. The right glove is now grasped by the left hand, already clothed, and the naked right hand introduced and the glove drawn into place, usually at the expense of dragging the left gloved thumb over the naked right hand and wrist. The surgeon now feels ready to begin his work or possibly deems it wise to rinse off his gloved hands in some sterile solution.

Another favorite method of putting on gloves is to throw several pairs of freshly boiled gloves into a bowl of bichloride of mercury solution or some similar antiseptic liquid. The surgeon, after thoroughly washing his hands as before, proceeds to draw or rather to float onto his hands the gloves lying in the bowl. During these manipulations he splashes the solution over the naked forearms and hands, the solution in turn bathes the gloves and smears over their outer surface, epithelium, etc., washed from the skin. The foregoing errors in technics are perfectly ap-

1 Received for publication March 7, 1904.

parent when they are brought to our notice, and that they are errors in fact and not hair splittings must be conceded by all who admit the truth of the first and most important reason for wearing gloves, namely, the uncertainty of being able to sterlize all hands every time for all operations.

If one accepts the above as a fact, and I think nearly all up to date surgeons do, what possible excuse can there be for allowing the discredited and suspected hand to touch and rub up against the outside of the gloves so carefully prepared? If the surgeon adopts gloves, he places himself in the ranks of those who believe that the hand cannot infallibly be sterilized. If he then puts on his gloves as I have described, he must be a traitor to his beliefs. Successful operative results in spite of these errors, do not nullify the argument. We see many perfect healings after operations where gloves were not worn, but the element of possibility of wound infection in the case of the naked hand has been proven by laboratory tests to be high and practically nil with the sterile glove. Why, then, place on the face of the glove the very material we so eagerly strive to imprison within the glove?

Another objection to putting on gloves that are immersed in some liquid, is the constant dripping from the wrist of the water imperfectly confined by the fingers in the interior of the glove. This water may have been lodged at the finger tips for some time and after having macerated and bathed the skin, a thoughtless change of level of the hand allows this impure liquid to escape at the wrist and in all probability to fall into the wound or its immediate vicinity. The same is true where a torn finger tip is used. The whole glove acts as a funnel, the torn or tipless finger serving as the small end to lead with unerring aim the sweat, detritus, etc., of the whole hand into the wound.

The actual preparation of the gloves is often very carelessly done and unless they are simply picked from the boiler with a sterile instrument and handed hot and wet to the surgeon there are many chances for error in their preparation by thoughtless and imperfectly instructed persons.

The writer believes that the best and pleasantest use of gloves comes from putting them on dry with sterile starch, or lycopodium as a lubricant. In order to have them perfect the writer prepares his gloves in the following manner: A wide-mouthed bottle filled with pulverized starch and provided with a piece of gauze tied over the mouth in a single layer, is sterilized in a live steam sterilizer. At the same time several towels are sterilized by live steam in the usual manner. The gloves are then turned wrong side out, placed in a wire cage and submerged in clean water in the ordinary instrument boiler. Care should be taken that all of the glove is filled with water and the air driven out. Two pair of long dressing forceps or sponge holders should be put into the boiler with the gloves. The gloves are allowed to boil for from five to ten minutes, they are then taken from the cage and allowed to drain hastily. With the sterile forceps the gloves are placed on one of the sterile towels spread out flat and another sterile towel laid over them. If all the free water has been allowed to drain from the gloves, a little stroking and patting of the upper towel will thoroughly dry the outer surface (really the inside, for the gloves were turned wrong side out) in a few minutes. The upper towel is then turned back and the gloves, both back and palm, thoroughly dusted with the sterile starch from the bottle.

We are now ready to turn the gloves right side out. With one pair of forceps the edge of the wristband is lifted and the other pair of forceps introduced into the glove until the blades can grasp the web between the middle and ring fingers; by drawing on the interior pair of forceps and turning the cuff over with the other pair, it takes but a moment to completely reverse the palm or hand portion of the glove. The neatest way to reverse the fingers is to grasp two diametrically opposed points of the edge of the wristband with the two pair of forceps, and then twirl the glove two or three times about its transverse axis; in so doing one closes the orifice of the glove and imprisons some air in the palm. Lay the glove with the orifice still sealed on a steril towel, and pressing on the balloon part of the glove with another sterile towel, the compressed air causes the fingers to be everted with a rush. The gloves are next dried on their outer surface by again stroking and patting with a sterile towel until they are perfectly dry. They are now placed in a sterile towel with a piece of sterile gauze about four by eight inches laid between the gloves, another piece of gauze laid on top and the towel folded over and pinned. By this method of preparation the gloves have only come in contact with sterile towels, sterile forceps and sterile starch powder. The inside is well lubricated, the outside is perfectly free from powder and as the gloves were perfectly dry when put away, they can be kept several weeks without deterioration.

To put on the gloves for use, the writer thoroughly cleans his hands and dries them on a sterile towel. The package of gloves is opened, one of the pieces of gauze laid in with the gloves is picked up and with it as a protector the edge of one glove is seized and the other hand thrust into the glove. The gloved hand picks up the other glove, using the second piece of gauze and the other hand is clad. The pieces of gauze prevent contact of any part of the naked skin with the outer surface of the glove. The dry starch serves as an excellent lubricant and if any adjusting of the finger tips is necessary, this is not done until both hands have been clothed. The whole procedure is very rapid and offers no excuse for a break in technics, and a little thought on the subject will, after one trial, make one perfect.

Let us then properly prepare our gloves, properly put them on and use only such as are perfectly watertight. The gloves are sterile only so long as we keep them so; they have no inherent virtue, no antiseptic power. One would think on seeing the carelessness with which gloves are handled

that they had properties similar to radium, emitting powerful bacteriacidal rays and were capable of neutralizing the grossest negligence on the part of those who abuse them.

INTERSTITIAL GINGIVITIS OR SCORBUTUS.[1]

BY EUGENE S. TALBOT, M.S., D.D.S., M.D., LL.D.,
OF CHICAGO.

A DISCUSSION before the British Epidemiological Society, February 19, 1904,[2] while seeming to involve the issue of treatment and prophylaxis really involved the issue of diagnosis. This issue is likely to be frequently raised since the American acquisition of colonial possessions requiring garrisons, and since the acquirement of the protectorate over the Panama Canal.

Mayer Coplans of the British army medical service found that scurvy appeared among a population which had been maintained on government rations of good quality. This population consisted of burghers in "concentration camps," European soldiers, natives attached to the British army and to the civilian repatriation department.

Each concentration camp contained about 5,000 persons, 48 per cent. being children under twelve years of age, and among adults the women were to the men as three to one. Inclosed by barbed wire the camps, though open and airy, were securely isolated. The conditions being identical the varying incidence of scurvy was remarkable. Between March, 1901, and January, 1903, with no cases at Standerton or Volksrust, there were one hundred Europeans and one native attacked. Among the soldiers at Standerton and the 22,000 European patients admitted to the hospital there was but one; among the natives in the service of the troops there were attacked 32 per cent. of 400 muleteers, 22 per cent. of those attached to the Hussars and the Royal Artillery, 87 per cent. of the scavengers engaged in removing carcases of animals, 17 per cent. of the porters and about 50 per cent. of the muleteers in the employ of the repatriation department.

The heaviest incidence of scurvy was after the close of the war, and when all restrictions on food had been removed. In fact, it had no relation whatever to the food, but was almost everywhere directly in proportion to the neglect of cleanliness, of which the natives had not the most rudimentary notions, especially as regards the hygiene of the mouth. Even the outbreak among the burghers at Middleburg followed overcrowding and neglect of sanitation. As to treatment, the food, though mostly preserved and tinned, was good, but many refused the harsh sour lime-juice. Dietetic treatment was very successful; rapidly so, if accompanied by mechanical cleaning of the teeth and gums with continued use of antiseptic washes, though more slowly without.

A. E. Wright said filthy habits were not peculiar to the Kaffirs and were not always accompanied by scurvy, which occurred in the nurseries of the rich and in nursing homes. Scurvy was essentially an acid intoxication, a reduction in the alkalinity of the blood, which could be observed long before the grosser manifestations, alike in the adult and infantile forms. A large proportion of the troops returning from South Africa were scorbutic in the latent stage. R. H. Hirth called attention to the low values of the dietaries given, few exceeding two thousand kilocalories, or barely enough for the body work. The ash of tinned milk was often acid instead of alkaline. In one expedition he had had to condemn 30 per cent. of the milk. A large proportion of British troops on return from "little wars" were more or less scorbutic. J. Land Notter said, the Kaffirs, though supplied with good food, preferred putrid meat or entrails of dead animals.

K. B. Goadby had not seen any scurvy at the Dreadnought Hospital, but had met much pyorrhea alveolaris, a disease endemic and occasionally epidemic in West and Central Africa, the Transkei, Philippines and other places. This condition of the gums and the rapid recovery of the patients under antiseptic measures resembled that found in scurvy. H. T. Bulstrode called attention to the fact that the great naval surgeon, Lind, had, one hundred and fifty years ago, rejected the belief in specific action of lime-juice. E. F. Willoughby was surprised at the absence of reference to the theory of Tonk, of Christiania, namely, that scurvy was no more or less than a chronic ptomain poisoning, which he considered the only one that explained all the phenomena of scorbutus.

Polar expeditions led to the conclusion that a diet of fresh, even raw meat, without any fruit or vegetables whatever and associated with hardship, dirt and misery, or one consisting entirely of tinned, preserved and sterilized foods of the highest quality, but with no fresh food, animal or vegetable, did not produce symptoms of scurvy, while scurvy appeared when along with potatoes, etc., and daily doses of lime-juice, the bulk of the food consisted of ordinary salt beef or pork. Until the recent Antarctic expedition from that of Nordenskjold in the Vega none had been attacked by scurvy except that of Jackson, whose men remained on board the ship, where they had lime-juice, potatoes, etc., but refused the coarse, even "gamy" bears' flesh on which alone the exploring party subsisted. All were attacked with scurvy, two, indeed, dying.

The Laplanders of Finland bartered for farinacea, etc., but ate their fish putrid by preference and suffered much from scurvy. Coplans pointed out in reply that it required months for its development, for the members of the corps that suffered most were recruited in their homes in October and the corps was dissolved in December, the disease breaking out soon after arrival in camp. Recovery followed rapidly on purely local treatment in the way of buccal antiseptics without any attempt to influence the blood.

The term "scurvy" frequently employed in the discussion is applied to the disease in the mouth,

1 Received for publication April 19, 1904.
2 The Lancet, London, March 5, 1904.

especially in relation to the gums. Nothing is said in regard to other symptoms and the logical inference is that such were not present.

In scurvy there is inflammation and bleeding gums. The gums puff up, thicken and bleed easily. The teeth become loose and sore upon mastication. A disagreeable odor comes from the mouth. Salivation or ptyalism results from irritation from the teeth as well as scorbutic anemia. The patient is languid or tires, perspires freely upon exertion, has shortness of breath and palpitation of the heart. The face is ashy gray, becoming paler each day. Hemorrhage takes place in different parts of the body, especially beneath the skin, in the muscles and beneath the periosteum as well as in the joints. This often gives considerable pain and sometimes causes inflammation with resultant pus infection. Occasionally hemorrhage takes place in the internal structures. The temperature varies and both febrile apyretic states occur.

The symptoms observed in interstitial gingivitis are connected with the gums and alveolar process. There are no constitutional symptoms. This disease was formerly known as pyorrhea alveolaris because the disease was not recognized until pus was observed about the teeth. It exists for years before pus is noticed. All the teeth may be lost without pus. Since the inflammation is deep-seated in the alveolar process as well as in the gums, I have designated the disease interstitial gingivitis. The interstitial gingvitis due to scurvy, drug or self-poisoning has the same pathology.

As part of the pathology, the character of the structures involved must be taken into account. In man's evolution, the face, jaws and teeth are diminishing for the benefit of the brain, under the law of economy of growth resultant on the struggle for existence between organs. Jaw recession is well illustrated in the American negro.

In man's evolution from the lower vertebrates, he has acquired two sets of teeth. Some of the lower vertebrates possess continuous sets. These are used for awhile, shed and new ones take their place. Man sheds the temporary set early in life. Should he live long enough the permanent set must be shed. This result is brought about by a process which takes place in the jaws of every individual, and has been designated osteomalacia or senile absorption.

Through the struggle for existence between organs and the eruption and shedding of the teeth, the alveolar process is a doubly transitory structure. Being an end organ it is a most sensitive structure easily affected by disease, drugs and faulty metabolism.

The age at which senile absorption begins depends upon the degree of normality of the individual. If he be neurotic or degenerate, or have inherited or acquired a cachexia or taint, this process of inflammation and absorption commences as early as the eighteenth or twentieth year. The process of shedding the temporary teeth and the eruption of the permanent teeth is a similar one, but the alveolar process holding the permanent set of teeth has not developed.

Interstitial gingivitis attacks every alveolar process after it has its growth, or about the twenty-sixth year. The severity depends entirely upon the degree of balance between the organs, including proper elimination.

At forty to forty-five, the fourth period of stress or period of evolution, the disease is quite active. From this time absorption is rapid and loosening of the teeth later occurs, even in comparatively healthy individuals. If the patient be constipated, have kidney lesions, skin or lung disease, so that any one of the eliminating organs are not doing the work, auto-intoxication results. The inflammation of the alveolar process is markedly increased. Other than improper elimination, no morbid condition will produce interstitial gingivitis, as surely as intestinal fermentations. Through want of proper secretion, starchy food is not properly digested and fermentation results. Gases accumulate in the intestines. The urine is excessively acid. Indicanuria is present with low specific gravity and urea is scantily excreted. None of these symptoms are severe, but merely render the patient uncomfortable. The physician rarely considers them of moment. They play havoc, however, as a result of auto-intoxication.

Auto-intoxication due to faulty metabolism, changes in climate and surroundings causing a want of proper adjustment of the excretory organs, no doubt produce the type of interstitial gingivitis before designated as "scurvy." The same results have appeared with the American soldiers in Cuba and the Philippines, and engineers and workmen building railroads in high altitudes in Switzerland. People going from a mild climate to an extremely hot or cold one, or vice versa, with or without change of food, do not readily adjust themselves to the new environment and the underlying states of interstitial gingivitis develop. Hygiene in Panama will be needed along these lines, since interstitial gingivitis increases, very disastrously, the morbid conditions to which in part it owes its origin.

Constitutional secondary consequences of interstitial gingivitis could, as Goadby evidently surmised, mimic scurvy, even as to the hemorrhages and here antiscorbutic treatment would be useless. It must be remembered that depression plays a part in this direction through its influence on elimination and alimentation. The defective metabolism of the insane, independent of diet produces hemorrhagic states. The first test of all these states is the gums, and here treatment with proper stimulus of elimination will aid assimilation and remove these "scorbutic" tendencies.

Influential Gastro-enteritis.—Physicians in Germantown report an epidemic of gastro-enteritis that is considered to be influenzal in origin. Children up to four years of age are attacked and there is usually accompanying affection of the respiratory passages. In addition to the diarrhea, vomiting and fever are present. The kind of milk or other diet used seems to bear no relation whatever to the onset of the disease.

SOME WEATHER OBSERVATIONS IN THE ADIRONDACKS.[1]

BY LAWRASON BROWN, M.D.,
OF SARANAC LAKE, N. Y.

THE weather observations upon which this paper is based were taken for about five years in the village of Saranac Lake, on a partially protected slope of about 1,550 feet elevation, with a western exposure. During the remainder of the time the observations were made at the Adirondack Cottage Sanitarium, situated one-half mile north of the village of Saranac Lake on a hillside with a northeastern exposure, at an elevation of 1,625 feet.

The Adirondack Mountains lie in the northern part of New York State between latitude 42° 30′ and 44° 30′, and longitude 74° and 75° 30′ W., covering roughly about 125 miles square. The average elevation is 1,600 feet, with peaks 1,000 to 3,000 feet higher, extending in general toward the southwest and northeast in several irregular ranges. The soil is composed chiefly of light sand, very porous, and glacial drift and moraines are common. Except along some of the more frequented roadways the whole region is rather densely wooded. Deciduous and evergreen trees occur in about equal proportions. A majority of the peaks and lesser elevations are wooded to the top and with each season present varying hues that render the landscape beautiful.

The whole region abounds in lakes and streams, which form one of its chief charms. Several rivers rise from these lakes, among them the Hudson, the Raquette, the Saranac, the St. Regis and the Beaver. The greater part of the shores and banks of the lakes and rivers are wooded to the very water's edge. Most of the

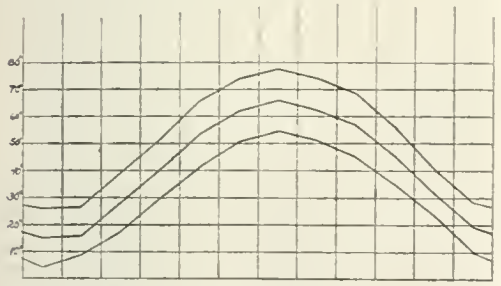

CHART I.—SHOWS MONTHLY MEAN OF MAXIMUM, MINIMUM AND MEAN TEMPERATURES AVERAGED FOR TEN YEARS.

lakes are small, but the Saranac lakes (upper and lower), Tupper Lake, Lake Placid and a few others, have a length of from five to ten or more miles. An idea of the frequency of the lakes and streams is conceived when it is known that one can start at Fulton Chain and go to Saranac Lake almost entirely by water, a distance of 100 miles or more, making short portages or "carries" between some of the lakes. The Adirondack region is well protected from the ocean by the White and Green Mountain ranges. Lake Ontario modifies the western slope, while the northern is under much the same influences as the St. Lawrence valley.

The Temperature of the Atmosphere.—The mean annual temperature for Saranac Lake was 41.57° F. for the ten years ending December 31, 1903. The monthly means varied from 14.98° for January to 66.24° F. for July, and are to be seen on Chart 1, as follows:

January	14.98°	(15)
February	15.62°	(16)
March	28.14°	(28)
April	40.65°	(41)
May	53.63°	(54)
June	62.50°	(63)
July	66.24°	(66)
August	62.84°	(63)
September	57.24°	(57)
October	45.67°	(46)
November	32.09°	(32)
December	19.23°	(19)

The mean maximum for this time was 52.47 (52) and the mean minimum 30.67° (31). The mean daily range was 21.8 (22), being greatest in the summer. January and February are the coldest two months with mean minimums of 3.98° and 4.76°. June, July and August are the warmest three months with mean maximums 74.23° (74), 77.86° (78) and 74.51° (75) respectively. The nights are always cool and it is rare that one does not require blankets.

The records show that during the period under observation a temperature of 90° F. has been recorded but 19 times, and during the last two years the thermometer has not reached that figure. On the other hand, on about 180 days each year 32° F. or less is registered. The highest recorded temperature is 95° F. on July 5, 1897, the lowest—38° F. on February 16, 1896. July is the warmest month and January the coldest.

The solar temperature has not been recorded.

Atmospheric Moisture. — The hygrometric state of the air has not been investigated. Last fall a sling psychrometer was used for one month, September 26 to October 26, at 8 A.M., 1 P.M. and 6 P.M. The average readings for this month were as follows:

8 A.M.	78.4 per cent.
1 P.M.	61.4 per cent.
6 P.M.	76.0 per cent.

Precipitation.—The average annual precipitation for ten years was 34.55 inches. The mean monthly precipitation was 2.88 inches and varied from 2.07 inches in April to 4.12 inches in July. The mean monthly figures are as follows:

January	2.29 inches	(2¼)
February	2.25 inches	(2¼)
March	2.80 inches	(2¾)
April	2.07 inches	(2)
May	2.95 inches	(3)
June	3.80 inches	(3¾)
July	4.12 inches	(4)
August	3.48 inches	(3½)
September	3.15 inches	(3¼)
October	2.70 inches	(2¾)
November	2.56 inches	(2½)
December	2.38 inches	(2½)

[1] Presented to the American Climatological Association, June 2, 1904.

The average yearly snowfall was 90.74 inches. A trace of snow fell in September, nearly an inch in October, 11 in November, 13 in December, 21 in January, 21 in February, 16 in March, six in April, and 1½ in May. From this it is seen that with the exception of June, July and August, snow falls every month, and averages for the year slightly more than 7½ feet. Consequently one-quarter of the precipitation (exactly 26 per cent.) is in the form of snow. The lakes and ponds are frozen from the latter part of November to March and at times the ice does not break up until May. These frozen waterways are used extensively for driving and hauling in winter.

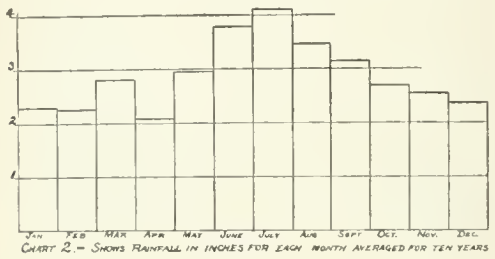

CHART 2.—SHOWS RAINFALL IN INCHES FOR EACH MONTH AVERAGED FOR TEN YEARS

It is of interest to note that April is the month with least precipitation (2.07) and July with the greatest (4.12 inches).

There is 0.01 inch or more precipitation on 145 days each year, or on twelve days out of each month. The average number of rainy and snowy days per month is as follows:

January	14.0	(14)
February	12.6	(13)
March	12.8	(13)
April	10.0	(10)
May	11.7	(12)
June	11.1	(11)
July	13.2	(13)
August	11.9	(12)
September	9.6	(10)
October	11.5	(12)
November	12.7	(13)
December	14.2	(14)

During December, January and February the precipitation is almost entirely in the form of snow. The number of rainy days in these three months are on an average about seven. During November and March, the snowy days (16) are nearly double the rainy days in number, while in April the number of snowy days (3) are considerably less than half the number of rainy days.

From these figures we gather that from the first of November to the first of April there is 0.01 inch or more precipitation on sixty-six days. Of these sixty-six days, rain occurred on fifteen days and snow on fifty-one days. Many of the rainy days were partly snowy.

The porous nature of the soil enables the rainfall to be rapidly absorbed, and many walks and drives are much pleasanter just after a rain. There are only a few clay beds in the Adirondacks and throughout this whole region there is but little soil of such a character as to retain moisture. A region of numerous bodies of water in the form of mountain lakes, with rocky shores and sandy beaches, differs materially, climatically considered, from a similar region with a heavy soil, retaining moisture.

Fogs and mists vary much with local conditions. In some localities they occur rarely; in others, along the rivers and on the lake shores, they are of more frequent occurrence. However, even where they occur, they are rarely seen except in the early morning hours. In the intense cold of winter, mists are seen occasionally along the unfrozen parts of the river.

The barometer readings for thirteen months show a mean monthly average of 28.412 inches. The highest monthly mean was in June (28.55), the lowest in February (28.22). The readings were taken indoors at an elevation of 1,550 feet.

September	28.521
October	28.377
November	28.405
December	28.160
January	28.331
February	28.224
March	28.373
April	28.400
May	28.460
June	28.547
July	28.435
August	28.412

The Sky.—The average number of clear days is 121.9, or 10.2 days per month. They are distributed as follows:

January	8.8
February	7.6
March	8.6
April	11.0
May	13.0
June	13.3
July	11.2
August	12.0
September	12.7
October	10.7
November	6.7
December	6.3

The number of clear days was larger than I supposed and compares very favorably with most "cool, moist climates."

The number of cloudy days slightly exceed the number of clear days and are 128.9 days per year. They occur as follows:

January	14.1
February	12.6
March	12.2
April	10.5
May	8.4
June	6.0
July	6.3
August	5.7
September	8.2
October	12.4
November	15.4
December	17.1

From this it is seen that the number of cloudy days is quite high, but on the other hand the

number of partly cloudy days is very small. The greatest number of cloudy days occur in November, December and January. The partly cloudy days number 114 and vary from 7.5 days in December to 13.5 days in July.

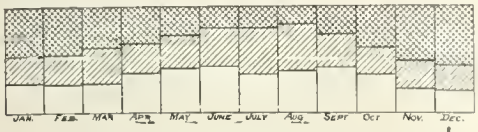

CHART 3.—PERCENTAGES OF CLEAR (BLANK SPACES); PARTLY CLOUDY (SINGLE HATCHING); CLOUDY DAYS (CROSS HATCHING).

The average percentage of possible sunshine for the last few years is 46.2 per cent. and is distributed as follows:

January	25.8
February	35.7
March	46.0
April	55.5
May	71.8
June	46.2
July	55.0
August	46.3
September	65.1
October	36.2
November	41.3
December	29.7

These records cover too short a time to be of value. The high percentage for May was due to the fact that last year a severe drought extended throughout the spring months.

Temperature alone, as is well known, does not express fully the effect of local conditions on persons of varying temperament. Coming to the Adirondacks regularly in summer from any of the cities of the Atlantic Coast one is impressed by the coolness and the amount of energy one feels like expending. In nearly all cases warmer clothes have to be worn. Permanent residents of the region seem to feel a slight rise of temperature in the summer much more than the visitors.

The purity of the air can almost be said to be a *sine qua non* of a pulmonary health resort. Many resorts, no doubt, owe much of their beneficial influence to this quality of the air. In general, the greater the elevation, the greater is the purity of the air. But other factors have to be considered, and among these are the density of the population, smoke, the velocity and frequency of the wind, and the condition of the soil. The first point is well illustrated by the following figures:

In London the number of solid particles in each c.c. of air is from 80,000 to 210,000, while that of the western highlands of Scotland is only 16.

The amount of dust in the air and ceteris paribus, the number of micro-organisms, depends largely upon the wind and the condition of the soil. The greater the velocity and frequency of the wind, the greater the quantity of the dust. For this reason forests which break the winds and which prevent them from reaching the soil are very valuable in preventing dust. Snow, too, is most valuable for this reason, for when the ground is covered with snow, there can be little or no dust. Rain, as has been often stated, is valuable both for precipitating impurities in the atmosphere and for preventing dust. No one, I think, will deny that the atmosphere in the Adirondacks with its 145 days of precipitation is well cleansed. From what has been said it can be easily seen that the greater part of the Adirondack region is wooded and has its climate modified accordingly. Further, the ground is covered with snow for a little over four months each year. The prevailing winds in the region about Saranac Lake are from the west, but with the exception of a few days in the spring and fall the wind causes little inconvenience to one leading an outdoor life. In summer on the eastern shores of the many lakes the cool breezes over the water modify the midday temperatures and are always refreshing, making the shores several degrees cooler than elsewhere in the same region.

In conclusion, it may be said that: (1) The climate of the Adirondack mountains is cool and moist during seven months of the year; cold and dry during five months. (2) The entire region enjoys freedom from dust and disagreeable winds. (3) The number of clear days is small, the number of cloudy days excessive, and the number of partly cloudy days much below the general average.

In closing, I wish to express my thanks to Dr. E. R. Baldwin, who recorded the weather observations for five years, and to Dr. Dutton and Mr. C. W. Mills.

Adirondack Cottage Sanitarium.

THE BIOLOGICAL INTERPRETATION OF CANCER.[1]

BY ALEXANDER SPINGARN, A.M., M.D.,
OF NEW YORK.

THE cellular theory of Virchow removed pathology from the domain of mystery and placed it within the realm of natural phenomena. It is to the science of biology that the students of disease now look for the laws that govern morbid processes. Can biology furnish a satisfactory explanation of cancer? This question is directed to the botanist and zoologist rather than to the pathologist and clinician.

The founder of modern pathology attributed disease to perturbations of the normal cells of the body. The bacteriological school, headed by Koch, have indicted the germ as the main culprit responsible for those changes in the activities and relations of cells which are recognized as disease. Hence a host of workers are looking for the special parasite of cancer.

The quest of this parasite, encouraged by success in cognate fields, must be lauded. Yet even if this attempt be successful, the discovery of the cancer parasite will no more explain the real cause of this disease than the bacillus of Koch reveals the genuine cause of tuberculosis. Prud-

1 Received for publication June 6, 1904.

den has ably emphasized the importance of viewing the microbe as the exciting and not as the efficient cause of disease.

In seeking the explanation of various natural phenomena pertaining to life, an appeal must be made in the long run to broad general biological laws. Of these, one which has unlocked many a mystery of science is the modern doctrine of evolution. Let this be applied to pathological as well as physiological phenomena, and in the present instance, to the problem of the origin of cancer.

The two important factors in evolution are heredity and variation, the latter including also the process of natural selection. These factors have been chiefly emphasized in the production of distinct types and species of animals. In no less degree have they been instrumental in establishing the form and type of the tissues and organs of the animal body.

The cancerous growth consists of the normal cells of the body, which have undergone an unlimited proliferation. Ribbert has beheld in this excessive multiplication of the cells an evidence of the loss of certain restraining factors whose influence is constantly felt in the normal body. As to what these restraining influences are or how they operate no suggestion has been made.

The real explanation of cancer should rather be sought in the laws that govern the growth and multiplication of cells. "If any one will tell me," says Prudden, "by what arrangement of cell mechanism, by what disposition of cell impulse, under what direction of heredity or environment, the various cells of the normal body go on growing, multiplying, taking on new forms and functions, framing new tissues, from the time the original cell ceases to be an egg and becomes an individual, until full maturity of the body is attained, if any one will tell me this, I say, and then tell me why at maturity this tissue growth ceases, why these new adventures in organ-forming stop and from maturity until the worn-out body is ready for the grave only those growths and replacements occur which are demanded by the exigencies of nutrition or accidental emergencies, I will agree to hand him back his lore as a fair clue to, if not an exhaustive exposition of, the origin of tumors."

The law of growth, so far as it is dependent upon the size of the cell, has been firmly established. The theorem of solid geometry that the surface of a sphere increases as the square of the diameter, while the volume increases as the cube of the latter, has been applied to the mechanics of the cell. As the cell grows its volume increases more rapidly than its surface. The nutrition of the cell depends upon its capacity to absorb. A stage is reached when the surface of the cell is incapable of absorbing sufficient nutriment for the cell-body, with the result that there is impaired nutrition, a weakening of the middle zone of the cell, a diminished resistance, with a resultant splitting along the weakened zone, which phenomenon is known as cell-division. This process is therefore dependent upon the ordinary laws of physics and geometry. But the latter determine only the limits to which a cell may grow. The absolute size of a tissue or organ, however, is dependent also on another factor, namely, the power or extent of multiplication possessed by the constituent cells.

At this point the law of evolution may be applied. This law has determined the absolute size of the various organs and tissues. While those organs whose size was inadequate to serve the needs of the body have caused the individual to succumb in the struggle for existence, so also organs which had a tendency to attain too great a size have proved a disadvantage to their owner. In the evolution of the complex multicellular organism, with the increasing perfection of physiological division of labor, there has resulted a fine adjustment of tissue to tissue and organ to organ. The health of the entire body would be an expression of the harmonious cooperation of the mutually interdependent members of the vital community, and might be termed an organic equilibrium. The researches of Jacques Loeb have shown that each tissue depends for its health upon the chemical equilibrium of its immediate environment. For example, the normal muscular contraction and the normal rhythmic beat of the heart are each dependent upon the delicate balance of inorganic salts in the surrounding medium, the blood. If one or more of these salts be increased, diminished or removed, there results a disturbance or an arrest of function. In a similar manner the nice equilibrium of the entire vital mechanism may be disturbed or even destroyed by the incomplete or excessive development of any one of its component parts. For instance, an excessively large heart would lead to inordinate arterial tension with consequent arteritis and possible rupture of the vessel. A similar tendency to proliferation and hypertrophy in the various tissues would lead to embarrassment of function. A familiar example of unchecked growth of a particular tissue is seen in lipomatosis or obesity. And just as the pathological, diffuse accumulation of adipose tissue hampers the workings of the bodily machinery, so a localized fatty infiltration of a particular organ (*e. g.*, the heart), compromises its efficiency. Moreover, one must not overlook the fact that a tissue which has acquired excessive proportions is apt to undergo, as the result of the failure of the body to supply adequate nutrition, degeneration or necrosis. In this manner may be explained the atrophy following the various forms of muscular pseudo-hypertrophy, the failure of compensation in an hypertrophied heart and the ulcerative transformation of malignant neoplasms. In the organic community overgrowth of any of its members is fully as disastrous as deficient growth. In the throes of the struggle for existence each tissue or organ has approximated, within certain narrow limits of conformation and size, to its ideal, or so-called normal, type. Natural selection would, therefore, account for the limitation of the size of

the different organs and tissues, which limitation is perpetuated by heredity.

At the same time, while recognizing this result of natural selection, one must admit that under certain conditions there may occur an overgrowth of tissue, a purely physiological hypertrophy. This is of a compensatory nature, and of the numerous forms a few may be cited, as follows: Hypertrophy of the heart, consequent to valvular disease or nephritis; overgrowth of connective tissue in the arteries, resulting from excessive blood-pressure (Thoma); the overgrowth of muscles to meet the demands of excessive exercise; thickening of the epidermis from increased pressure; compensatory enlargement of one kidney, lung, or one cerebral hemisphere from absence or defect in the corresponding mate, etc.

The above examples show the plastic character of the vital mechanism, which unlike any other known structure, changes its size and power according to the demands made upon it. Structure and function may be mathematically expressed as the functions of a number of variables, such as use, environment, heredity, etc. "Life in all its forms," says Henry Maudsley, "physical and mental, morbid and healthy, is a relation; its phenomena result from the reciprocal action of an individual organism and of external forces; health is the consequence, and the evidence of a successful adaptation to the conditions of existence, and imports the preservation, the well-being, and the development of the organism, while disease marks a failure in organic adaptation to external conditions and leads to disorder, decay and death."

In this adaptive capacity of the individual tissues and organs is to be sought the secret of pathological hyperplasia. One may here allude to the conservative tendency displayed in connective tissue formation. The closing in and the final obliteration of a tuberculous cavity in the lung by connective tissue, is a familiar example. This conservative or protective tendency is again seen in those numerous forms of hypertrophy resulting from embarrassment of an organ or tissue. Thus results hypertrophy of the heart in adherent pericardium. The formation of callosities on epithelial surfaces exposed to constant pressure, is a case in point. If for any reason the cells of the tissues, as the result of some irritation, be prevented from exercising their proper activity, there is a tendency to increased cellular multiplication. This subject is closely connected with the fundamental problems of regeneration of cells and tissues. In his work "Regeneration," Morgan alludes to a phenomenon that most students of biology must have observed in the laboratory, namely, that starfishes sometimes replace one lost arm with two new ones. While it is true that in most cases the part which is formed by regeneration is identical with the part lost by mutilation, yet it would seem as if, in some instances, the forces, whatever they may be, that make for regeneration, are ever ready, upon the slightest embarrassment or injury of a part, to assert themselves with a momentum out of all proportion to the original loss. The application of this fact to the problem under discussion is plain. There are a number of protective mechanisms in the body which are probably closely related to the regenerative faculty. Thus the increase in the number of red blood cells that rapidly occurs when the individual ascends in a balloon or takes up his residence in the mountains, occurs in response to the deficient oxygenation attendant upon the rarefied air, the increased number of red blood cells enabling the body to get the normal supply of oxygen; in addition, each red corpuscle is larger. The erythrocytes are being constantly destroyed in the organism and constantly regenerated. Under normal conditions the power of repair proceeds at a rate which is just sufficient to keep the number of red blood cells constant or approximately so. Yet in response to the increased needs of the organism this regenerative capacity may be increased. It is conceivable that certain stimuli which have no relation to the needs of the body, might bring about this increased proliferation of red blood cells. The phenomena connected with the formation of cicatricial tissue serve to illustrate both the normal and the abnormal phases of regeneration. Thus, while the scar-tissue is ordinarily just sufficient to close up the wound and in this respect represents the normal type of regeneration, yet, under certain conditions not yet understood but probably consisting in abnormal irritants or stimuli, the cicatrix may become excessively large and troublesome, constituting what is known as keloid. The formation of exuberant callus in fractures is another instance of this same extravagant and riotous regeneration.

The leucocytosis that occurs in inflammatory processes is probably fundamentally akin to the above-described phenomena, being but an augmented and accelerated reproduction of white blood cells in response to bacterial and toxic irritants. This prodigal multiplication of leucocytes has been turned to good account by the organism in a protective way. The hyperplasia of the bone-marrow, spleen, and lymphatic glands, with the associated enormous leucocytosis that occurs in the various forms of leucemia, may be analogous to the above-mentioned types of unchecked and abnormal regeneration. It is quite possible that future investigations will show that the production of anti-bodies in the various forms of acquired immunity, is but a phase of the accelerated proliferation of elements normally present in the economy.

The formation of galls, tumor-like excrescences produced in plants by insect parasites, indicates regenerative phenomena analogous to those above mentioned. The presence of the insect stimulates the plant cells to multiply at an abnormally accelerated rate, with the result that a mass is formed which completely encapsulates the parasite. It is supposed that poisonous irritants secreted by the insect are the cause of this abnormal cellular growth. It is suggested by Darwin that possibly chemical compounds secre-

ted by plants under changed conditions of life, may cause eccentricities in the growth of various parts of the plant, similar to those seen in insect-galls. This phase of the problem under discussion invites thorough experimental investigation.

The explanation of these forms of hypertrophy may be sought in the fact that when the cells of a tissue are incapable, as the result of some irritation, be it chemical, parasitic or mechanical, of doing the work allotted to them, then these cells will proliferate, in order to produce other cells, the activity of which will make up for the embarrassed function. The rôle that mechanical irritation or traumatism plays in the etiology of malignant neoplasms has not been overestimated. The possibility that chemical or toxic irritants, the result of faulty metabolism, may act as tissue irritants in this respect, must be considered.

August Weismann, in his fascinating book, "Essays on Heredity," speaks of the inherent immortality of the cell. The lowly animal organism, consisting of a single cell, endowed with the unlimited capacity to subdivide, knows not death. It is only the multicellular animal in which immortality has been restricted to the reproductive cells. Death is the result of natural selection. Possessing originally an infinite capacity to subdivide, the cells of the body have eventually acquired a finite existence, and the entire body itself has been doomed to death, as the result of the struggle for existence between the individual cells, as well as between the different animals. The cessation of life is an adaptation to the conditions imposed by the crowding of cells and animals, with the consequent reduction of the means of subsistence. The reason, therefore, why a particular tissue keeps on growing until it has reached a certain size and complexity, and then stops growing, is thus easily explained on the basis of an adaptation to the functional and nutritional needs of the living environment. But the tissue never forgets its birthright. Endowed with a capacity to grow which has been stilled by the needs of the organism, this capacity of the tissue is again awakened whenever anything tends to embarrass or limit the activity of this particular part.

"It is rather a matter of surprise," says Prudden, "that ever-changing, self-regenerating living tissue does not oftener go astray in its activities than that it only now and then should do so." May not the proliferative aberrations in cellular life be compared to the numerous examples of reversion to an ancestral type familiar to the student of zoology? The reversion in this case would be to the habits of the cells at the dawn of life, either of the race or of the individual, when self-multiplication was the most prominent phenomenon in cellular activity.

That there is some ground for believing in the atavistic origin of new growths is indicated by the recent researches of Farmer, Moore and Walker, reported to the Royal Society. These investigators detected in the depth of malignant tumors certain peculiar cells which are exactly like those that are formed during the early stages of division of the germinal epithelium, resembling the latter in having but one-half the usual number of chromosomes in the nucleus. This observation does not necessarily confirm Cohnheim's hypothesis of the embryonal origin of tumors, namely, that certain displaced embryonal cells, when the conditions are favorable, are prone to multiply with all the energy characteristic of their prototypes, for the authors have not been able to cause the development of new growths by transplanting portions of ovarian or testicular tissue to different parts of the body. It indicates rather that in the course of the mitosis of highly differentiated cells, some of the latter, by a peculiar process of cell-division, may revert to the primordial condition of the cells in early embryonic life.

In discussing the proximate causes of reversion, Darwin states "that any change in the habits of life apparently favors a tendency, inherent or latent in the species, to return to the primitive state." If this is true of the entire body, it is probably also true of the constituent cells. That the highly differentiated somatic cells should inherit the remote ancestral traits of the undifferentiated germinal cells, in most instances, only during the latter part of the individual's life, is in line with some of the well-known phenomena of atavism. "Thus," says Darwin, "the calves of a hornless race of cattle which originated in Corrientes, though at first quite hornless, as they become adult sometimes acquire small, crooked, and loose horns; and these in succeeding years occasionally become attached to the skull." Other instances of the incidence of atavism during advanced periods of life are cited. What is still more interesting is the observation that frequently this tendency to reversion may become hereditary.

The question now arises, namely, how can one reconcile with the atavatic conception of cancer the hypothesis that the abnormal and excessive proliferative activities of the cells seen in neoplasms, are the result of changes in the environment, *e.g.*, irritation. The explanation seems to be close at hand. All physiological manifestations occur in response to some external stimulus. Life is but a series of reactions of a collection of unstable compounds known as protoplasm to external forces. Every pathological manifestation is likewise to be attributed to some external stimulation. In the production of vital manifestations the play and counter-play of numerous forces must be borne in mind. Factors such as heredity, nutrition, climate, crowding, etc., all share in the elaboration of the finished living product. Would it seem so strange, therefore, that the normal, modest deportment of the bodily cells, in keeping within the strict limits decreed by the struggle for existence, should at times be upset by some new factor that disturbs the peace of the vital community? Just as a severe psychic cataclysm may transform the highly civilized individual into a

savage, so an unusual stimulus or a congeries of stimuli may excite certain bodily cells to assume the habits of their primitive ancestors. In cancer the stimulus may be a jagged tooth, a traumatism, a long-continued ulceration; it may be some chemical poisons originating in the wear and tear of the tissues, and only effective after years of accumulation (hence the incidence of cancer during and after middle life); it may be that the law of habit exhibited so powerfully in the life of the cells, decrees that when the units of protoplasm belonging to a certain lineage have frequently responded in the past to various stimuli by taking on an abnormal proliferative activity, then the cells of the same lineage will be prone to respond in a similar way in the future. Thus the rôle of heredity in cancer may possibly find its explanation.

640 Willoughby Avenue, Brooklyn.

APPENDICITIS: PATHOLOGY AND SURGICAL TREATMENT.[1]

BY EDWARD N. LIELL, M.D.,
OF JACKSONVILLE, FLA.;
FRESIDENT OF THE FLORIDA STATE MEDICAL ASSOCIATION; FORMERLY LECTURER ON DISEASES OF WOMEN, NEW YORK POLYCLINIC MEDICAL SCHOOL.

The fascination of abdominal surgery and the brilliant results achieved stimulates our attention to the importance of appendicitis. As its etiology and pathology have been more closely defined, so has its treatment advanced, and the morbid specimens removed frequently afford an opportunity for interesting study.

It is axiomatic that no surgical procedure should be advised or adopted except there be a reasonable hope that it will result in cure or marked relief to the patient. Moreover, I desire to emphasize the fact that needless delay in operating is a factor leading to increased mortality; unfortunate results have followed operations performed as a last resort. The diagnosis having been made, surgical rather than medical care is demanded.

We know nothing definite as to the pathological process which would warrant delay in operating; were surgical intervention a prompt procedure, that is, operation on the first or second day of the attack, practically all cases of appendicitis could be saved. In every fatal case of appendicitis there has been a period in which the patient could have successfully undergone the operation. There is no other major surgical operation which is so reasonably sure of success, symptomatically as well as surgically, after early operation and when prompt interference means as much to the patient.

In a series of fourteen cases of appendicitis, of varied type, in which I have been called upon to operate within the past six years, it was my misfortune to lose two. These, however, cannot be attributed to the operator, they being operations of emergency—suppurative and perforative, and which I was called in haste to perform out of the city. Were it a question of a surgeon's percentage, mortality and recoveries, my better judgment would have dictated not to operate in these cases; it was the desire of the attending physicians and the parents of both patients that I should give the possible chance, which I proceeded to do. In operations of emergency, even though death be invited, one cannot always decline to operate.

The two cases in which death occurred are of interest. In one, a girl aged thirteen years, the disease was fulminating in character, of but three days' duration. The appendix was of a diameter of one's thumb, gangrenous and sloughing at its base, with honey-combed pus pockets and adhesions profuse; septic peritonitis was in evidence. A hard fecal endolith, the size of an orange seed, was found in the middle third of the appendix, a condition which in the early days of appendicitis had given rise to the theory of orange, lemon or cherry pits as the chief factor in etiology.

The other case, a young man aged nineteen years, temperature 103° F., was what I term one of sacculated suppurative appendicitis, an appendiceal abscess with protective adhesions, in which I removed fully a quart of fetid pus. The abscess cavity was thoroughly irrigated with hot normal salt solution, drainage being continued by means of iodoform gauze strips carried through an opening left unsutured in the abdominal wound, the sac not being removed.

This case was certainly a remarkable instance of appendiceal abscess with protective adhesions, in which the sac contained a quart of fetid pus, which had been forming for some days. The patient's vitality was at a very low ebb at the time of operation. In this instance is emphasized what I have already referred to, the fact of needless delay in seeking operative interference.

Regarding the cases in which recovery ensued, several are of interest pathologically and because of attending complications. In one, there was associated intestinal obstruction, a loop of the ileum within a foot of the ileocecal junction, being found strangulated and cyanosed by a fibrous band one inch in length and the diameter of a goose quill, running from the stump left of the broad ligament, following an oophorectomy eight years previously, to the middle portion of an elongated and inflamed appendix. The fibrous band was ligated with catgut at the old stump, and the appendix including the band ligated with silk and removed, the patient being subsequently entirely relieved of all untoward symptoms. The diagnosis in this instance was one of intestinal obstruction with probable appendicitis, the patient having presented symptoms of the former especially only three days previous to operation.

A second case, a young man aged twenty-eight years, was of rapid development. The appendix was acutely congested and in part gangrenous, bordering on perforation near its apex; temperature 102.4° F. at the time of operation. The omentum was much injected and in great part adherent, a portion of it being ligated and removed;

[1] Read at the Third Annual Meeting of the Atlantic Coast Line Surgical Association, Jacksonville, Fla., November, 1903.

the appendix had a broad base with firm mesentery attachment.

Two cases were complicated with right interstitial salpingitis, the appendix and the fimbriæ of the tube in each instance being intimately adherent. The right tube and ovary as well as the appendix were removed in both cases; and in addition, in one of these I performed a myomectomy for subserous fibroma, the size of a lemon, located on the posterior wall of the uterus. Not infrequently we find the appendix unusually long and adherent along its whole length to the cecum, and even curving around the latter. In such instances it is by no means an easy matter to free the appendix from its attachments.

Silk is the material which I always use as a pedicle ligature; I have never departed from it; furthermore, I always make positive that my ligatures are both well placed and reinforced, to avoid any possibility of secondary hemorrhage.

Regarding pathological changes in the appendix, the investigations of Fraser after repeated experimentation upon rabbits, have given the following results:

1. Suppurative appendicitis ensued as a result of obstruction of the lumen through aseptic ligation of the appendix.

2. Closure of the lumen in regard to the virulence of infective germs normally contained in the appendix, proved that such is capable of converting an inoffensive into a most virulent organism, the post-mortem findings showing also marked pathological changes in the walls of the appendix, gangrene being present in a portion of the cases.

3. Closure of the lumen, a foreign body being contained therein, gave results identical with No. 1.

4. In the unobstructed lumen a virulent culture in the presence of chemic irritation gave a negative result; as did also a virulent culture in the presence of a foreign body.

5. Ligation of the vessels produced marked structural changes, undoubtedly due to a lessened resistance whereby an infection, which otherwise would be innocuous, obtains a permanent foothold. Foreign bodies do not cause appendicitis unless infection ensues, and only become a menace when associated with obstruction of the lumen.

As regards the pain in appendicitis, Tripier has formulated the law, confirmed by experience, that none of the affections of the abdominal viscera are accompanied by attacks of pain unless the surrounding peritoneum is involved in some acute or subacute inflammatory process, and that the pain is more intense the smaller the quantity of the fluid exudate. Considering the variations in the position of the appendix a constant pain at McBurney's point is not to be expected. One should be guided by the severity of the symptoms present, ignoring the absence of symptoms usually present.

Elevation of temperature, while a necessity to diagnosis, is no indication of the degree or extent of the pathological process. Preconceived ideas based upon experience often prove valueless, as a positive opinion prior to operation cannot be given as to location, attachment or condition of an appendix.

BEGINNING GENERAL PARESIS, ITS RECOGNITION AND MANAGEMENT.[1] [2]

BY CHARLES LEWIS ALLEN, M.D.,

OF TRENTON, N. J.;

PATHOLOGIST AND ASSISTANT PHYSICIAN, NEW JERSEY STATE HOSPITAL, TRENTON, N. J.

A DISEASE which has as its result the desolation both mental and physical of its victim, would seem to call imperiously for early recognition and treatment, to the end both of staying its progress as much as possible, and of forestalling the dangerous consequences to family and community resulting from the foolish, reckless, and often violent actions of a person impaired in his powers of self-control, reason and judgment. Such a disease we have, in that chronic degenerative affection of the nervous system, known as dementia paralytica, the progressive paralysis of the insane, general paralysis or general paresis.

While probably not a new disease, its recognition as a clinical and pathological entity dates back only about eighty years, and even to-day there are some authorities who maintain the idea of its duality, as Regis when he speaks of paralytic dementia, and paralytic insanity. It was formerly regarded as quite rare, a case in this institution having been visited as a curiosity as recently as thirty-seven years ago.

This is hard to understand, in view of its prevalence to-day, for unhappily it seems to be growing in frequency. Statistics vary considerably, but the following from the Vienna State Asylum are most striking. In 1838, general paresis constituted 12.6 per cent. of all the cases admitted; in 1867 the figure had risen to 18 per cent.; while during the ten years ending in 1897, it had reached the proportion of 30 per cent. of the total admissions.

In this country it is undoubtedly less frequent, its proportion to all cases of insanity being stated at from 6 to 10 per cent. In the New York State institutions, it constituted in 1901 8.6 per cent. of 4,916 admissions, while in 64,609 admissions, since 1888, it was present in a trifle over 7 per cent. of the cases. The disease is much more common in an urban than in a rural population, and many more men than women are affected, though this latter varies from a proportion of two men to one woman in some parts of Russia, to one to seven or one to ten in this country, while in an entirely rural population the disproportion may be even greater. Among women of the better class it is relatively rare.

General paresis has been pithily styled by Krafft-Ebing, a product of "civilization and syphilization," and in its production syphilis

1 Read at a meeting of the Mercer County Medical Society, March 8, 1904.

2 Received for publication April 5, 1904.

seems to play a most important if not the chief rôle, the number of cases in which previous syphilis can be shown being estimated all the way from 25 to 90 per cent. Abuse of alcohol is undoubtedly an etiological factor, but its importance is much disputed. Alcohol carries in its train its own special forms of mental disease, among them one which closely resembles general paresis. It certainly does act as one of the sources of overstimulation of the nervous system, and in its not uncommon association with syphilis it may have a decided influence. However, as one of the early symptoms of general paresis is a tendency to indulge in alcoholic, as well as in other excesses, there is liability to confound cause and effect.

Heredity for insanity or nervous disease may have an influence, though as to this again opinions diverge widely. The modern struggle for existence with its tendency to produce both mental and physical stress, through overwork, excitement, and intemperance in eating and drinking, appears to be chiefly responsible for the increase in general paresis. These comprise the main causes of this disease. General paresis, however, cannot be considered a direct manifestation of brain syphilis, for while its lesions are of fairly definite character they differ from those of syphilis proper. It can at best be considered like tabes, a metasyphilis. The ravages of the disease are not confined to the brain, but may extend to any part of the nervous system, and after death other organs are also found to be affected. It is doubtful, however, if the latter lesions should be considered as properly belonging to general paresis.

In a disease of so varied and irregular distribution, it is small wonder that a complex clinical picture should be presented. Broadly speaking, however, the two features which stand out are progressive mental failure, and paresis of muscles, more or less extended. It is a disease preeminently of the prime of life, men from thirty to fifty years old being its chief victims. It is not unknown outside of this period of life, however, and the juvenile cases especially seem to be growing in frequency. These nearly always occur in the victims of hereditary syphilis. Cases have been reported at as early a period as ten years of age, while in the seventh decade the disease is not unknown. No grade of society is immune, for it attacks high and low, among both preferring those of convivial habits, in whom syphilis and alcoholism are apt to be present. In the great majority of cases the disease begins slowly, and there is a period more or less prolonged, during which the patient's mental condition seems to be undergoing a change, though perhaps definite derangement is not apparent. The victim may show more or less marked exaltation of spirits, with abandonment of care, excitability with irritability and restlessness, or, on the other hand, vague depression and fears, or hypochondriacal ideas. As a rule he sleeps badly.

Again, the first symptom to be noticed may be a change in conduct. The previously sober, moral and prudent man plunges into alcoholic and sexual excesses, squanders money in unnecessary, foolish, and extravagant expenditures, and may even resort to trifling fraud or theft to obtain articles which he could perfectly well procure in a regular way. In form the disease varies greatly, and these variations overlap one another, but in practice it is usual to recognize three general types:

1. *The Dement Type,* in which the symptoms are those of a progressive mental failure without marked depression or excitement, or definite delusions.

2. *The So-called Classical Type,* where there is exaltation and excitement, with increased feeling of well-being (euphoria), rising to grandiose delusions, such as of unrivaled strength, fabulous wealth or supreme power. The patient has begotten 1,000 children, owns millions of money, is king of kings, etc.

3. *The Melancholic Type,* characterized by depression, sleeplessness and hypochondriacal ideas. To these are sometimes added an agitated, periodical and ascending type, the second being characterized by changes of mood from excitement to depression and vice versa, and the last beginning like tabes, with loss of power in the legs and ataxia.

One and all, however, proceed ultimately to the same issue of dementia, ending in death in marasmus, unless the victim is cut off by some intercurrent disease, or dies in a convulsive seizure. The dement type has of late years been growing more common, and to-day is by far the most frequent, the classical form being the exception rather than the rule. For the general practitioner, however, it is the first stage of the disease which is of importance, for he it is who sees the patient at this time, and if he recognizes the probability of what is to come he may be able to preserve the victim from courses which can only hasten the fatal outcome, and to protect the family from the humiliating, indeed, often the tragic results, of the misconduct of its now irresponsible head. The public, too, is to be considered, for instances of swindles, great and small, of abuse of authority on the part of military and naval officers, or of judges or others in high positions, of criminal assaults, and even of murders, by persons in the early stages of general paresis are unfortunately far from rare.

What are the earliest symptoms? There is no one which taken alone is characteristic, but a probable diagnosis is to be based upon the combination of certain mental and physical changes, with due consideration of the age of the patient, his position in society, and his previous history, especially as regards the likelihood of former syphilitic infection.

As a general proposition, in any mental disturbance arising in a man between the ages of thirty and fifty years, who has no history of having shown mental unbalance earlier in life, the possibility of the case being one of general paresis should at once present itself. If there is a clear

history of previous syphilis, the possibility becomes a probability. In women of corresponding age the idea of general paresis does not suggest itself so prominently, but, nevertheless, the social position and previous life of the patient is to be taken into consideration, and with the history of exposure to syphilization the probability of general paresis becomes strong.

We have under observation at present an interesting instance of so-called conjugal general paresis. The husband was admitted suffering from general paresis, within the year the wife following him with the same disease. Each presents an example of the dement type, but in the case of the woman, the disease is running a more rapid course than in that of the man. The history is fragmentary, but the woman has on her lip a well-marked cicatrix, possibly the former seat of a chancre.

The further removed from the age limits mentioned the patient may be, the less the probability of the disease, though it is not excluded, as both juvenile and senile cases of paresis are not unknown. From what has been said above, it will appear that the mental symptoms of general paresis vary widely, and to make a diagnosis from them alone is seldom possible. Whether the patient is depressed or exalted, or exhibits expansive delusions, with or without motor excitement, there is generally, however, an underlying defect of intelligence, shown in loss of memory and power of judgment, which, though it may be difficult to elicit, can usually be brought out by careful questioning. Delusions when present are not built up logically—though from false premises—and defended with plausible arguments, as in the case of the paranoiac, but are unsystematized, changing from hour to hour, and often at once suggestive by their immensity and grotesque absurdity. Hallucinations are exceptional and there is lacking the true maniac's rapid flight of ideas. Upon the combination of somatic signs with mental symptoms, however, we depend for the differentiation of general paresis from other forms of insanity.

At this point it is well to emphasize the fact that by general paresis or general paralysis, we mean a definite disease involving both mental and physical spheres, in persons at the prime of life, and not the gradual loss of power often with mental failure observed in old people, generally as a result of arteriosclerosis, and consequent nutritional changes in the brain. This distinction, there is reason to believe, has not always been made with sufficient sharpness, by the profession in general. As was stated above, paresis of muscles more or less extended is to be considered as an essential feature of the disease. This shows itself in the inability to perform certain functions properly. The symptoms most likely to be found in the earliest stages are alteration of the knee-jerk, failure on the part of the pupil to react for light, and optic atrophy. A combination of one or all of these with mental change, provided its presence cannot be explained on other grounds, makes the diagnosis practically certain. It will be noticed that the eye symptoms with loss of knee-jerk are indicative of locomotor ataxia, and in fact an exceedingly close relationship exists between this disease and general paresis. Both seem to follow, in the vast majority of cases, a syphilitic infection more or less remote. Both attack especially men in the prime of life, but in the one the somatic symptoms are predominant, and the mind may remain clear, while in the other the mental symptoms soon come to the front. The question of the relationship of these two diseases is interesting and much discussed, but cannot be entered into here. Suffice it to say that while mental symptoms may occur both as a result, and as an accidental complication of tabes, a middle-aged person showing mental alienation, with loss of knee-jerk and of the pupillary light reflex is in the vast majority of cases afflicted with general paresis. The ataxic symptoms may long antedate the mental change, as shown in the case of a man thirty-five years of age, recently observed, who presented a characteristic picture of tabes, and had his complaint so diagnosed by a number of physicians, nearly three years before the advent of definite mental symptoms, the onset of convulsive attacks, and speedily developing marasmus made the diagnosis clear. On the other hand in a man demented since a psychosis in early life, tabes developed just beyond middle life and he died after thirty-seven years' residence in the hospital at the age of fifty-nine years, having at no time shown the picture of general paresis.

It must be remembered, however, that loss of knee-jerk may be due to any lesion which interrupts the reflex arc for the qudriceps extensor, whether situated in the muscle itself, in the nerve, or in the lumbar enlargement of the cord. It is a common symptom in multiple neuritis, and occurs in myelitis of the lumbar segments, and in some brain tumors. Again the knee-jerk may be sometimes lost in diabetes, and in Bright's disease. In the majority of cases of general paresis, however, the knee-jerk is exaggerated, on one or both sides. This exaggeration is of much less diagnostic value than loss of knee-jerk, since it may be present in a number of other conditions both functional and organic, and when not too marked is not a symptom of great importance. In not a few cases of general paresis, there is degeneration of the lateral columns of the cord, as in spastic paraplegia, and again both lateral and posterior columns are affected.

Where loss of visual power is apparent, an ophthalmoscopic examination should be made—if necessary by an eye specialist—for optic atrophy is an important symptom in this connection, provided its other causes can be eliminated. The characteristic pupillary anomaly is failure to contract for light, while contraction for accommodation remains. This condition known as the Argyll-Robertson pupil, is very suggestive, and may be present long before other symptoms are manifest. In a study of 17,000 patients, Thompsen, of

Bonn., found that of those showing the Argyll-Robertson pupil, 90 per cent. either had tabes or general paresis. Some caution is needed, however, in eliciting this symptom, the light should be good and should fall evenly upon the eyes. The presence of an old iritis which has caused adhesions, and interferes with the enlargement of the pupil, would be shown by its irregular outline. Difference in size of the pupils is also a sign of some importance, but of much less value than immobility, since slight differences are not infrequently congenital, or again are due to changes in the sympathetic innervation or to bygone iritis. The immobile pupil is generally a narrow one, although not always. In young, anemic, and nervous persons, the pupil is wide as a rule, but it tends to become narrower as age advances.

The earliest symptom of impairment of muscular power is incoordination, as shown by tremor and inability to perform certain movements. Specially characteristic are the disturbances of speech, and of handwriting. The speech disturbance, which is due to the incoordination of the muscles of the tongue and lips, consists in inability to properly bring out and combine syllables into words—the "syllable stumbling" of the Germans, for instance, instead of artillery the patient may say "ratrillery," etc. Syllables may be left out, slurred, or transferred. Where the patient's memory has become very defective, he cannot remember a word long enough to repeat it after another person, but may bring out only the first syllables. The voice is apt to become monotonous, and its pitch may be changed, generally lowered. As the patient tries to speak, there is often observed, what Clouston calls "the fatal tremor," about the lips, which is very characteristic. Speech can best be tested by asking the patient to repeat after you such words as abnormality, artillery, truly rural, etc.

Disturbances of handwriting which may occur comparatively early, are due to muscular incoordination, and to failure of memory, lack of attention, and indifference on the part of the patient. Berkeley declares that the first irregularity is apt to appear in the upstroke of the letters, which tends to present a sawlike edge. The letters are also apt to be uneven in size, and not in the same horizontal plane. Letters and syllables are left out, and blots are frequent. Defective innervation, and twitchings of one side of the face, paresis of the eye muscles, and so forth, have also some diagnostic value, but they also occur in other conditions, and their interpretation is attended with considerable uncertainty. In the developed disease, however, there is a heavy masklike expression, which is very characteristic.

Local anesthesias and paresthesias may also be present, but are not always easy to elicit. An old test for general paresis is inability to smell pepper. A symptom which does not properly belong to the early stage of the disease, but which is not infrequently the first thing to call attention to the serious nature of the case, is the occurrence of a paretic seizure. This, when it occurs in a case otherwise suspicious, clinches the diagnosis. It may take the form of a slight vertigo, easily mistaken for fainting, or may vary from a slight twitching of certain muscles, as of one side of the face or of one hand, to a general epileptiform convulsion. Again the attack may have an apoplectiform character, and be accompanied by rise of temperature, and congestive symptoms, and may leave behind a weakness of one limb or of one side of the body, which, however, generally clears up in a few days or a week.

The interpretation of such attacks is often difficult, but in a man in middle life, if previous epilepsy, trauma, alcohol or other poison and uremia can be excluded, and focal brain symptoms are absent, the probability of their paretic origin is very strong. Again, a paretic seizure, as a rule, differs from a true epileptic fit. The patient frequently does not entirely lose consciousness, and the convulsion is much more apt to be partial or Jacksonian in character. In an apoplectiform attack occurring for the first time some caution is necessary in forming an opinion. These comprise the chief symptoms to be expected in the early stages of general paresis. No one alone is characteristic, but two or three combined may enable us to form a positive opinion.

Practically the one disease from which it is most important to differentiate general paresis in its early stages, is neurasthenia, with predominant cerebral symptoms. This latter is also a disease of middle life. In it hypochondriacal ideas and depression, with loss of sleep, irritability, headache and vertigo, and tremor of the muscles of the face, tongue, lips and fingers may occur, as they do in general paresis. There may be reduction of mental capacity in both diseases, but in neurasthenia there is simply weariness, and no real mental failure. The neurasthenic will not present loss of knee-jerk, but rather exaggeration, and his pupils are not immobile. The neurasthenic as a rule feels worse in the morning, and improves toward night, while in the paretic, the reverse is the case. Lastly in neurasthenia there may be a history of a constitutional neurosis dating back to early life, while in the paretic there is apt to have been previous syphilis. Hoch states it as his opinion that of those breaking down from excessive stress, in the middle period of life, those who have had syphilis will probably develop general paresis, while those who are free from specific taint will be neurasthenic.

The two other conditions which are most likely to be confounded with general paresis, are cerebral syphilis, and chronic alcoholic insanity. In each there may be mental failure with or without delusions, convulsive attacks, and perhaps speech disturbance, and paralyses. Cerebral syphilis, however, as a rule, occurs nearer the primary affection than does general paresis, and headache and focal symptoms are apt to be present. Alcoholic pseudo-general paresis may resemble general paresis quite closely. The knee-jerk may be lost through an accompanying alcoholic neuritis, but the pupillary changes are generally wanting,

and under enforced abstinence, the symptoms are apt to clear up either wholly or in part.

To recapitulate briefly: Severe neurasthenic, or hypochondriacal symptoms, or any decided mental change coming on without known cause in a man from thirty to fifty years old, should be regarded as suspicious. If there was previous syphilis the probability of general paresis is great. If in addition there is immobility of the pupils, with loss of knee-jerk, the diagnosis is practically certain, while if to the above there are added the characteristic speech disturbances, and a convulsive seizure, there is no longer any doubt.

The diagnosis once established, the prognosis is of the worst, the fatal result being only a question of time. The average duration of a case of general paresis is from two and a half to three years. Some cases—the galloping form—run their course in a few months, however, while in others the disease extends over years. There is now under my care a typical case of the tabetic type, which has certainly existed for ten years, while a recent writer has reported a case which had lasted sixteen or more years. Again there are remissions which may extend over one or two years, during which time the patient seems almost well, and these probably have given rise to reports of cured general paresis. Unfortunately we have no specific treatment for the disease, and are reduced to treating symptoms as they arise. Its prevention is directly connected with that of syphilis, and with the thorough treatment of that disease when it occurs. The theory of an intoxication, or a disordered chemism of some sort as a causative factor, is held by some authorities, but our information on this subject is at present too meager to allow us to formulate an adequate line of treatment.

Bruce claims to have procured amelioration by injection into a paretic of the serum of another paretic who was in a remission. Donath says that he has produced marked improvement in six paretics by the injection of massive doses of a rather complex solution of salts, but these methods are not yet on an established basis. A course of antisyphilitic treatment may be tried, but has usually been found of little use, if not deleterious. General tonic treatment, with mild hydrotherapy, combined with measures to procure proper sleep, may be of benefit.

The chief duty of the physician, however, is to guard the patient from alcoholic and sexual excesses, and to see that his strength is in every way husbanded, and that he is kept from excitement and worry. In a family which can afford to pay for a trained attendant, a case of the dement type may possibly be managed at home, but early interment in a good institution, under constant and intelligent care, is by far the safest and cheapest measure. Even for a case with severe neurasthenic symptoms, where the diagnosis is in doubt, a sojourn in a sanitarium, where restorative treatment can be carried out and where precautions against any eventuality can be taken, is strongly indicated.

THE BACTERIOLOGY OF PANOPHTHALMITIS.[1]

BY RICHARD H. JOHNSTON. M.D.,
OF BALTIMORE, MD.;
ASSISTANT SURGEON AND PATHOLOGIST PRESBYTERIAN EYE, EAR AND THROAT HOSPITAL; DEMONSTRATOR OF LARYNGOLOGY, UNIVERSITY OF MARYLAND SCHOOL OF MEDICINE.

FROM the observations of several investigators, it seems an established fact that Fraenkel's pneumococcus is the most frequent cause of panophthalmitis. While in some cases a mixed infection of pneumococcus and staphylococcus or pneumococcus and streptococcus has been found, the pneumococcus is probably the essential etiological factor.

Gaspanini, Uhthoff, Hansell, Bocci, Mündler, and Schwartz have all obtained such results. Hirota has reported three cases of panophthalmitis, all of which he ascribed to the pneumococcus. The first case was one of hypopyon keratitis with perforation and panophthalmitis and mucocele. Twenty-four hour cultures showed numerous pneumococci and few staphylococci. One-half c.cm. of pneumococcus bouillon injected into a white mouse caused death in twenty-four hours: Pneumoccocci were found in the blood. One-half c.cm. of staphylicoccus injected into a white mouse caused death in thirty hours. Nothing was found in the blood. Cultures two weeks later produced the same result.

In the second case, there was a mucocele. Cataract operation was followed by wound infection. Cultures showed pneumococci and few staphylococci. One-half c.cm. pneumococcus bouillon injected into a white mouse caused death in twenty-two hours. Injection of staphylococci had no effect. Three weeks later, pure cultures of pneumococci were obtained. In the third case there was also mucocele. Pure cultures of pneumococci were obtained, which, when injected into a mouse, caused death in twenty-two hours. From the pure culture of the pneumococcus in one case and from the results of animal inoculation, the author concludes that the infection by the pneumococcus is the essential cause of panophthalmitis.

In all three of his cases a mucocele was present in which he claims is often found pneumococci. As is well known, this organism is the most frequent cause of ulcus serpens corneæ. In the last few months two cases of panophthalmitis have been examined bacteriologically at the Presbyterian Eye, Ear and Throat Hospital. The first case was wound infection and panophthalmitis following cataract extraction. The operation was performed under the usual antiseptic precautions on a colored man who some weeks before had had an attack of pneumonia and had apparently entirely recovered. There was no mucocele, the conjunctiva appeared healthy, and the operation was perfectly satisfactory.

The next morning, less than twenty-four hours after the operation, the wound was seen to be infected and the eye was soon full of pus. Smears from the pus showed scattering diplococci. Twen-

1 Received for publication May 27, 1904.

ty-four hour cultures revealed diplococci in abundance. Three c.cm. of a bouillon culture were injected into a guinea pig. The animal died twenty-two hours later and smears from the heart's blood showed encapsulated pneumococci. Cultures from the other eye and from the blood were negative as to the presence of the pneumococcus. Later cultures were always pure pneumococci. In this case the pneumococcus was certainly the direct local cause of the infection.

The other case was Panophthalmitis from a knife injury. Smears from the pus showed nothing. In twenty-four hour cultures pneumococci and staphylococci were found. Inoculation experiments on guinea pig gave pneumococci in the blood. In this second case the essential cause seemed to be due to the malignant pneumococcus. The results confirm those of the authorities named above. Dr. Darling, of the city health department, has recently informed me of a case of panophthalmitis caused by the pneumococcus.

Now that the cause of the disease has been established it behooves us to use our best endeavors to prevent such infection. According to Randolph, the normal conjunctiva always contains organisms, the commonest species being the *Staphylococcus epidermidis albus* of Welch, a coccus resembling the *Staphylococcus pyogenes albus.* Lawson found the normal conjunctiva to be sterile in twenty per cent. of cases and pyogenic cocci to be rare, and, when present, non-virulent. Other observers have stated that the conjunctiva is generally sterile. It is probable that organisms in the normal conjunctiva are non-virulent, and in order to prevent infection following cataract operation, it would seem advisable to ascertain whether or not the pneumococcus is present. If so, the operation could be deferred for a time and measures taken to get rid of so malignant an organism. The saving of one eye from infection would be worth the trouble entailed in the taking of cultures and of animal inoculations.

Hirota's observations have shown that a mucocele increases greatly the danger of pneumococcus infection. It would be a simple matter to investigate this disease for the same organism. It is our duty as oculists to take every precaution to prevent infections of all kinds and especially the pneumococcus infection which has undoubtedly caused the loss of not a few eyes. I firmly believe that by bacteriological examination, we can at least decrease the number of cases of panophthalmitis following cataract extraction.

819 Park Avenue.

Mortality for July.—The deaths for July were 1,958, 213 more than were reported in June, and 432 less than July, 1903. The death rate for the month was 11.95 per 1,000. The deaths under one year were 122 less, and those between one and five years 106 less than in July, 1903. The Health Department attributes the low mortality to propitious weather and a remarkably good water supply. Acute intestinal diseases heads the list of death causes, with 333; consumption comes next with 233, and then follow violence, with 184, Bright's disease with 144, heart diseases with 143 and pneumonia with 123.

AUTO-INTOXICATION OF GASTRO-INTESTINAL ORIGIN [1]

BY CLIFTON MAYFIELD, M.D.,
OF WASHINGTON, D. C.

That the character of gastro-intestinal digestion bears mightily upon the intensity and progress of most diseases, is, I think, a statement that will go unchallenged, and that this is the prevailing opinion is proven by the exactness of diet invariably outlined in sickness.

The question then is, Why? and to me the answer seems to be that, either because of a diminished digestive activity, or because of already existing gastro-intestinal disease, the fermentative changes so prone to take place in the digestive tract, become exaggerated.

These changes, the result of chemical processes and bacterial activity, cause the disengagement of gases, especially sulphureted hydrogen, and of potassium and ammonia and also of certain organic toxins and ptomains (allied to the vegetable alkaloids) that are reabsorbed into the circulating media and prove poisonous to the animal cells to a greater or less extent, dependent upon the amount absorbed on the one hand, and on the other upon the rapidity of excretion or of their destruction by the liver.

In acute febrile and eruptive diseases; in most chronic affections, notably renal and cardiac; in neurasthenia and other and better defined conditions of the nervous system; in insanity, and, indeed, in most pathogenic states, the condition of gastro-intestinal digestion with its possibly resulting greater or lesser degree of auto-intoxication, has a bearing upon prognosis and treatment that must not be ignored.

This condition of auto-intoxication is, I believe, as much of a reality, vastly more important and many times more frequently demanding our attention, than the poisoning that supervenes upon the taking into the body of decomposing food products. There is this great difference, however. In the case of the poisons generated within the digestive tract their production is comparatively slow, and when their elimination is normally affected their removal is as rapid as their production, and the system does not become overwhelmed.

Paul Paquin says, relative to the various products of food decomposition and excrementitial matter, "Individually, collectively or associated, they are more or less grave factors in modifying our happiness and safety. In classified diseases such as typhoid or scarlet fever, etc., or any malady reducing nervous control and special functions of the cells of the digestive apparatus; indeed, in any condition lowering the general defensive power of the organism as a whole, the microbes of the digestive tract may become most damaging enemies."

In an article upon "Relapse in Typhoid Fever," read before this society and published in the *Virginia Medical Semi-Monthly*, April 11, 1902, I

[1] Read at a meeting of the Medical and Surgical Society, District of Columbia, May 5, 1904.

called attention to the fact that under the stimulus of the toxin of typhoid fever the normal intestinal inhabitants may become virulent. May it not as well be the case—and to me it seems more than plausible—that under the stimulus of other toxins, as in acute infectious diseases and influenza, the increased activity of normal intestinal germs accounts for many of the indications of auto-intoxication? Certainly the evidences of the presence of gastro-intestinal catarrh would give support to such a theory.

Gastro-intestinal auto-intoxication may result from the ingestion of decomposing food; from the fermentation or decomposition of food within the alimentary tract; or from reabsorption of bile or fecal matter.

The condition arising from the ingestion of putrefactive material may be properly classed under the head of true poisoning, not auto-intoxication, but the remote results arising therefrom would constitute a true auto-intoxication, and to this I will later call your attention.

In faulty digestion there are produced acid and nitrogenous compounds that have been shown to be poisonous. So long ago as 1790 Hufeland, in his work, recognized the condition of auto-intoxication from fermentation and putrefactive changes of food in gastro-intestinal disease. But probably to Bouchard more than to any other investigator must be given the palm for painstaking observation and research into this most interesting subject, and in particular as to the significance of the presence in both the digestive tract and the excretion of the kidneys of certain compounds, the products of bacterial energy.

To him is due the credit of showing the relation of indol in the intestines to indican in the urine, and that this relation is, to a certain extent, constant.

While indol, phenol, skatol and other products cannot be found in the fetus, pointing to the fact that they are the result of germs entering the digestive tract after birth, yet their presence afterward is so constant as to entitle them to be considered normal products of normal bacterial action. Their presence becomes abnormal when shown to be in excess, either by reason of overproduction, or because of incomplete destruction or elimination.

Indol, the product found in largest quantity, is thought to be the result of the activity of the colon bacillus, and shows disturbing effects upon the heart and produces degenerative changes of the liver. Phenol and skatol are found in much smaller quantities, and the source of their production has not, so far as I have been able to find, been determined. Cholin produced from food rich in lecithin is but slightly toxic and occurs particularly when the lower end of the small intestine is occluded. Neurin produced by further action upon cholin is intensely poisonous, increasing intestinal movements and having a paralyzing effect upon the heart.

Pasteur, some years ago, showed the existence in the mouth, stomach and intestines, of bacteria that produce fermentation and putrefaction and elaborate ptomains and toxins, which, absorbed, cause according to dose and rapidity of absorption, acute or chronic poisoning.

These poisons are usually eliminated chiefly by the kidneys except when that emunctory is unequal to the task, either because of the diseased condition of the organ, or because the poisons are formed with a rapidity too great to permit them to act efficiently.

By numerous experiments, that the scope of this paper will not permit me to present, it has been shown that the liver has a very important office to perform in the destruction of these poisons, taken up by the portal circulation, and that the indol in the hepatic vein is much less than in the portal vein. When, under such conditions, the liver is overworked, there ensues a condition of engorgement—so-called biliousness—and, continued into a chronic state, we may have cirrhosis.

The amount of indican in the urine bears to the indol of the intestines an approximately fixed relation, but is not as true a measure of albuminous decomposition in the intestines as the latter, for indican shows only the amount of indol absorbed in the intestines which reaches and is excreted by the kidneys, and is, therefore, the true measure of indol less the amount destroyed by the liver or carried from the bowels in the alvine discharges. The amount of acid in the stomach has ordinarily but little bearing upon the production of indol, as most of the bacterial action by which this body is elaborated takes place below the ileocecal valve and the acid secretions are neutralized before reaching this point, except in marked cases of acid fermentation.

Potash and ammonia salts, as well as ptomains and toxins, are poisonous to the animal cells. Meat fiber contains these salts developed in the process of tissue metabolism, and it was an observation of this fact that caused Liebig to characterize beef tea as not only lacking in nutritive value, but as being actually poisonous.

It is a matter of common observation that constipation gives rise to many of the evidences of auto-intoxication, and yet the theory of self-poisoning is to a certain extent doubted by some because, they reason, the drier the fecal mass the slighter the opportunity for reabsorption and poisoning. As a matter of fact, constipation exists largely because of diminished peristalsis and the slower passage of the fecal mass to its resting place pending evacuation, is attended by increased absorption of its fluids and with these fluids there enter into the circulation coloring matter of bile, potash and ammonia salts and ptomains and toxins in force. At the same time it is true that the condition most favorable for auto-intoxication is the semi-diarrheal state attended by one or two loose movements a day, for here the amount of fluid is large and the chances for absorption proportionately increased.

The effect upon the system of these abnormal products is dependent in large part upon the degree of perfection of the process of elimination,

particularly by the kidneys; and before proceeding further I wish to call attention to the important bearing of auto-intoxication of gastro-intestinal origin to renal disease.

There is no more indispensable organ of excretion than the kidney; no source of auto-intoxication more prolific than the gastro-enteric tract. Therefore, if the first is damaged it becomes of the gravest importance that the digestive tract, absolutely necessary for body nutrition, may not be transformed into a factory and supply depot for materials to poison the body, with no compensating emunctory to eliminate the poisons thus produced.

In violent diarrheal conditions, as in cholera morbus and cholera infantum, the rapid withdrawal of fluids from the body may result in suppressed kidney function and a coincident auto-intoxication, not on account of the great excess of toxins absorbed, but of their accumulation in the system by reason of failure of elimination.

As already stated, the liver acts as a barrier to the entrance into the system of ptomains and toxins, and when, by reason of failure of the liver to do its normal work, or by reason of the demand being beyond the normal liver capacity to work, ptomains and toxins enter the system and auto-intoxication ensues in inverse proportion to the effectiveness of kidney elimination, with resulting headache, irritability, fatigue, muscular soreness, hypochondriasis, vertigo, neurasthenia, lethargy, stupor, insanity, cutaneous affections such as pruritus, acne and urticaria, asthmatic attacks, and functional disturbances of the heart.

Bouchard states that the ingestion of the extract of 2.5 gm. of decomposing meat is sufficient to kill a man.

When decomposing meat is taken into the stomach the symptoms are violently acute if the ptomains exist in sufficient quantity. Such would be a case of true poisoning, the system being overwhelmed as in the case of large doses of the vegetable alkaloids, and the termination should be equally acute; but as a matter of fact, when so-called ptomain poisoning occurs it is rather the active bacteria than the ptomains taken that cause the disturbance; here some hours must elapse before marked evidences of poisoning appear, and this constitutes a true auto-intoxication. The process of decomposition begun and but slightly advanced in the food is prolonged and intensified in the digestive tract, absorption goes on with a rapidity too great for elimination, and we have the symptoms of acute auto-intoxication. It is more than probable, too, that bacteria already existing in the stomach and intestines are, in this bath of toxins, stimulated into increased activity and form no inconsiderable portion of the enemy making the assault.

In a variety of chronic affections of the stomach and intestines there appear evidences of poisoning by toxins and the absorption of the products of acid fermentation and the gases and salts of intestinal decomposition. In cancer of the stomach and intestines; in chronic dyspepsias gastric and intestinal; in chronic diarrhea; and in dilatation of the stomach are found the before-mentioned indications of auto-intoxication.

Personal idiosyncrasy to certain foods is, I believe, rightly considered a condition calculated to bring about a true toxemia after the ingestion of such foods. Probably every one here has seen cases of this kind. The indulgence of certain individuals in strawberries, fish, crabs and numerous other foods that are recognized as foods that "disagree with them," is invariably followed by such symptoms as nausea, vomiting, headache, fever, eruptions in the shape of hives, etc. It would seem that the use of such foods, as also of those repellent to the stomach, whether such distaste is the result of disease or personal dislike, is attended by rebellion of the stomach nerve supply against them,—exactly as the special senses rebel against things disagreeable to them,—digestion in inhibited fermentation or decomposition ensues and we have a typical, though not severe, auto-intoxication; not severe because the liver, bowels and kidneys are equal to the task of protecting the organism against the sudden assault. Where these organs are diseased and defective we may have more severe and even fatal results, and such, I believe, is the true condition in many cases of sudden death in aged, and even young persons, with weakened hearts.

It has also appeared to me that the more chronic condition of auto-intoxication may contribute largely to the characteristic deaths of many of the aged. Such cases usually begin with disturbed heart action without preexisting heart lesion, unless we consider arteriosclerosis, which normally exists in old age; then follows some degree of asthmatic breathing and increasing weakness; the urine is loaded, showing evidences of faulty metabolism; sleeplessness passes into somnolence; the tongue is coated and the breath offensive; the bowels are in a fluctuating condition of constipation and diarrhea; and the temper is more and more irritable. With ever-increasing disinclination for food and more and more evidence of failure of the digestive function, death finally ensues in a few months. Yet, study the case as you will, you can find no one or more organs affected to a degree necessary to account for the end.

To-day the surgeon, as a matter of routine, prepares his patients for operation by the preliminary administration of a cathartic, the evident purpose being to clear the intestines of waste material, and in this he does wisely, for the intestines are thus, in large part, relieved of bacteria and toxins, and the possible complication of toxemia from this source is reduced to a minimum.

My attention has been called a number of times to a class of cases dying after operation for appendicitis in which there appeared no local nor well-defined general condition to account for such a termination. One such patient of my own I had an opportunity to observe and the symptoms were those of profoundly disturbed digestion and heart terminating shortly before death in coma.

The local condition was apparently all that could be desired, and the case, to me, seemed to be one of gastro-intestinal auto-intoxication.

Increase in the frequency of epileptic seizures, attending excessive feeding and resulting imperfect digestion, is such a common occurrence as to call for mere mention.

It has been claimed that during chronic toxemia there is a progressive lessening of the bactericidal power of the blood serum; and if such is true we can readily understand to what an extent such a condition would add to the gravity of various diseases.

Dr. Otto Kauffman says that certain nervous disturbances and organic nervous diseases can be explained by gastro-intestinal auto-intoxication.

Dr. Hubert Work says that loss of weight and anorexia occur so constantly in connection with certain pschycoses as to suggest a common cause. Further that it is certain that insanities do result from prolonged digestive disturbance and that auto-intoxication from the alimentary canal may alone cause many cases.

Dr. Forbes Robertson considers toxic action the most frequent primary etiological factor in the production of insanity, and in this connection insists upon the paramount importance of the gastro-intestinal tract. He believes that toxemias from this source are important factors in the production of various acute and chronic diseases; cases of dementia; locomotor ataxia; general paralysis; senile insanity; chronic alcoholic insanity; idiopathic epilepsy; most cases of acute and chronic mania and melancholia; and chronic Bright's disease. He believes that the majority of cases of insanity are not primarily diseases of the brain, but the result of toxins from other sources which affect the brain cells, disorder their metabolism, and more or less permanently damage, or even destroy many of them.

There is one quite fashionable disease to which I would invite special attention. Neurasthenia, like malaria, is ofttimes a cloak to cover a multitude of sins, whether of lack of observation, or of catering to the whimsicalities of patients who dislike to be told, even in polite terms, that they are paying the penalty for past gluttony, but much prefer, indeed, are pleased, to be told that they are neurasthenic. Understand, I do not deny the existence of a true neurasthenia, or, as I interpret it, fag of brain and nervous system from business worry or too great mental effort, but I do believe that the majority of such cases are nothing more or less than faulty digestion with resulting ptomains and toxins in excess. The symptoms most prominent are such as may be found in a less degree in chronic dyspeptics and the greatest, and, indeed, almost the only benefit to be derived is from means calculated to abate the gastro-intestinal disease and its resulting auto-intoxication.

There has ever prevailed with the medical profession a dread of the use of laxatives in typhoid fever; yet, believing in the effect upon the typhoid infection of a coexisting gastro-intestinal auto-intoxication, the result of bacterial activity and of constipation when the latter exists, I have frequently found excellent results to follow the cautious administration of calomel.

I propose to say but little on the extensive subject of treatment, and that only in general terms, for the time at my command will not permit a detailed consideration of this part, and very important part, of auto-intoxication.

The conditions to be met are: (1) Avoidance of the introduction of foods most liable to fermentation and putrefactive changes, and of substances already undergoing such changes; (2) the lessening or destruction of bacterial energy within the gastro-enteric tract; and (3) relief of the system from toxins, ptomains and products of acid fermentation, either by rapid removal before absorption, or by aiding their excretion by the usual organs of elimniation.

The avoidance of foods in a condition of fermentation or decomposition however slight is, of course, imperative.

A much harder question to determine is the correct diet adapted to the varying conditions of disease of the digestive organs, a question that can only be settled after a proper consideration of each case under treatment. It is safe to say, however, that in all cases foods rich in starch and sugar are to be avoided, because of the ease with which they undergo fermentative changes; and also such foods as are hard to digest, which latter give the greatest opportunity for bacterial development and the production of toxins.

It is likewise necessary to avoid too frequent and excessive feeding, for foods easiest of digestion given in too large quantities, overtax the digestive function, perhaps inhibit it entirely, and thereby afford opportunity for fermentation and decomposition.

The effect of drugs administered by mouth or rectum upon bacterial energy or life is, to say the least, rather uncertain. Various remedies, for example iodine, creosote, carbolic acid, naphthol, iodoform and charcoal, as well as many others, have been recommended. I believe I have run the gamut, only to fall back upon creosote and charcoal, the former in moderate, the latter in large doses, as seeming to be of most service.

Stomach and colon washing I have found quite valuable in removing the offending agents. By means of the stomach tube remains of undigested food, the product of fermentation, gases and bacteria are removed and the organ left in far better condition for the next food ingested. No one who has ever used the stomach tube with any frequency has failed to observe repeatedly how certain symptoms in catarrhal and those dilated conditions of the stomach that so much distress the patient, disappear and how bowel conditions are benefited also.

Colon washing is likewise valuable, though for obvious reasons it cannot be carried out so thoroughly as stomach washing. Inasmuch as bacterial activity is greatest below the ileocecal valve, and because the washing will often remove fecal

accumulations not touched by laxatives, we would naturally expect, and usually find, that colon washing when thoroughly done proves of marked benefit.

Unfortunately these two methods of washing reach but a part of the digestive tract. Toxins in the small intestines will be absorbed, at least, in part, and upon the rapidity and effectiveness of their destruction and elimination by liver and kidneys depends to a certain extent the degree of auto-intoxication. The small intestines are swept and liver engorgement relieved by occasional mild laxatives, thereby at the same time lessening the amount of poison to be absorbed and increasing the functional activity of the liver.

The effectiveness of the kidneys is increased by moderate indulgence in water—but very sparingly during meals; complete prohibition of alcoholic liquors; and careful regulation of diet. The skin must also be kept in good condition by baths and proper clothing.

The great difficulty in the way of preventing and overcoming the condition of auto-intoxication lies in the lukewarm assistance or direct antagonism of the patient, and to such should always be made clear the fact that the fight will be one of long duration and will call for the greatest patience and most persevering attention to details.

BACTERIURIA, WITH SPECIAL REFERENCE TO COLI BACILLURIA.[1][2]

BY ARTHUR R. ELLIOTT, M.D.,
OF CHICAGO.

The constitution of human urine renders it an almost perfect medium for the growth and multiplication of lower forms of organic life. As a consequence, we find that to an unusual degree the urinary tract is subject to attack from bacterial forms of life, the resulting suppurative and infective processes possessing, with hardly an exception, the characteristic of excessive obstinacy. It is not the purpose of this paper to consider the bacteriology of the urine, but to discuss the comparatively little known condition termed "bacteriuria," the term being employed in the sense originally used by Roberts (*British Medical Journal,* 1881, Vol. 2, p. 359), to designate certain cases in which the urine is the seat of infection by microorganisms without the urinary mucosa sharing in the process.

Recent discoveries have added much to our knowledge of the excretion of disease germs by the kidneys in the various systemic infections. It has long been known that toxins were excreted by the kidneys in most, if not all, diseases of infective nature, but until recently considerable difference of opinion prevailed as to the elimination of specific disease bacteria themselves, unless gross lesions of the kidneys existed; in other words, unless the filter was leaky. This point is now fully established. A breach of continuity of the renal structure need not exist. The most important of the infective agents eliminated by the kidneys in disease are the typhoid bacillus, *Bacillus coli communc,* pneumococcus, and the tubercle bacillus.

The typhoid bacillus is present in at least one-fourth of all cases of typhoid fever, often in enormous numbers, in some cases the urine being a pure culture of the germ. The virulence of the bacillus is retained, being equal in one case observed by Richardson to that of a culture from the stools and internal organs. Pneumococci have been found in the urine in large numbers in pneumonia during the height of the fever (Kleinmann). The tubercle bacillus has been repeatedly demonstrated in the urine without pus being present in cases of miliary tuberculosis. Phillipowicz (*Wiener med. Blätter,* 1885, No. 22) discovered the bacillus of glanders and of anthrax in the urine of animals suffering from those diseases, and was able to cultivate streptococci from the urine in erysipelas and ulcerative endocarditis. Pyogenic cocci have been repeatedly demonstrated in urine free from pus, and Schweiger (*Virchow's Archiv,* Band 100, Heft 2) has proved that the urine of scarlatina and varicella may carry contagion.

While this elimination in the urine of specific germs in infective systemic conditions undoubtedly constitutes bacteriuria in the broad significance of the word, it is not within the meaning of the term as ordinarily used in clinical medicine.

The term bacteriuria, as originally employed by Roberts and Ultzmann, and as understood in clinical medicine, is meant to imply an infection of the urine by bacteria from some source within or tributary to the urinary tract itself. A distinction is therefore to be made between such cases and those instances just reviewed, in which the urine acts merely as a vehicle for removal of disease germs from the system. For a clear understanding of the condition known as bacteriuria it is equally important to eliminate those frequent infections of the mucous membrane of the urinary organs in which the urine teems with bacteria thrown off from their nidus of growth in the mucosa.

The symptom known as bacteriuria is therefore to be defined as a condition in which bacteria are excreted in large numbers in a pus-free acid urine, without any sign or symptomatic indication of cystitis or infective nephritis. When first voided the urine is cloudy, often lactescent and gives forth a putrid, revolting smell, which has been likened by Moullin to the stench of stale fish. The turbidity of the urine when voided, and the penetrating offensive odor are the characteristic symptoms of the condition. The opacity does not settle to the bottom of the vessel on standing, and cannot be separated by sedimentation in the centrifuge or by filtration through paper, although the urine may be rendered clear by passage through a porcelain filter or by thorough shaking with magnesium usta.

1 Read at the Fifty-fourth Annual Meeting of the Illinois State Medical Society, Bloomington, Ill., May 18, 1904.
2 Received for publication May 24, 1904

The reaction of the urine is acid, and under the microscope the field is seen to be swarming with actively motile organisms. The sediment is small and contains no pus, or but a few rare pus leucocytes are to be discovered. Local urinary and general systemic symptoms are generally absent. In most of the cases observed this has been the rule, although a minority have shown vesical irritability, urinary incontinence (especially in children), and occasionally digestive and nervous symptoms have been present. The bacteria are mainly the *Bacillus coli commune*, often in pure culture. Jeanbeau (*Gazette des Hôpit.*, June 24, 1899) collected 67 cases from the literature, in 56 of which the *Bacillus coli commune* was the infective agent. In the remaining 11 it was streptococcus, *Proteus hauseri*, or *Bacillus subtilis* alone or in combination. Barlow (*Deut. Archiv für klin. Med.*, Bd. 59, p. 347) gathered together from the literature and his own experience notes of 65 cases of bacteriuria. In these, *Bacillus coli commune* was present 19 times—17 in pure culture, twice with staphylococci. Of the remainder, sarcinæ were present in 22 cases, staphylococci in three cases; in the remaining two, undetermined bacteria.

In five cases occurring within the writer's experience within the past two years, the *Bacillus coli commune* was the predominating bacteria, associated in three of the cases with common pus organisms.

Concurrence of clinical experience is in favor of the *Bacillus coli commune* being present in the great majority of cases, frequently in pure culture, sometimes associated with pyogenic microorganisms. The importance of the coli bacillus in the urine may be easily overestimated, because of the great frequency of its occurrence as a secondary infective element in suppurative diseases of the bladder and kidneys. In infective urinary diseases different forms of pus organisms may be abundantly present at first, and subsequently become entirely replaced by coli bacilli, which, because of their rapid growth, hide the original pathogenic microbe. This is undoubtedly the origin of many cases of coli bacilluria.

In the majority of cases of *Bacillus coli* infection of the urine there seems no difficulty in understanding how the organism gains access to the bladder. The path of infection is apparently the urethra, since urethritis, instrumentation or injection have usually preceded the bacteriuria. The writer is inclined to reject the idea of a direct infection by way of the urethra, normal or diseased. Undoubtedly the frequently preceding urethritis stands in a certain casual relationship to the coli infection; not, however, in the writer's opinion, so much by direct infection of the urine *per urethram*, as indirectly, by preparing the soil through gonococcal involvement of the prostate and seminal vesicles, the subsequent coli bacillus invasion occurring from the bowel through the lymphatics into the inflamed prostate or vesicles. Coli bacteriuria is a comparatively frequent complication of gonorrhea, especially of cases in which the deep urethra and prostate have become involved. Fuller (Diseases of the Male Sexual Organs, Lea Brothers & Co., Phila., 1895) particularly has called attention to the frequent existence of *Bacillus coli commune* in the seminal vesicles in chronic gonorrhea. The above view of the invasion of the urinary tract receives support from the fact that operations upon the rectum, fissures, fistulæ and hemorrhoids, all of which involve a breach of integrity of the rectal mucosa, and prostatic congestion from irritation, predispose to coli bacteriuria, and in practical experience have been known to give rise to it without urethral aid. Additional testimony is afforded by the frequency of coli infection of the urine in prostatic hypertrophy during the later years of life. Moreover, the almost complete monopoly of this disease by the male sex incriminates the prostate and seminal vesicles.

That the bacteria in cases of bacteriuria find their way into the bladder by way of the urethra is negatived by certain well-known facts. The *Bacillus coli* is one of the common inhabitants of the glands and foreskin, and of the vulva (in 50 per cent. of women, according to Melchior), and Winslow (*Journal Med. Research*, Boston, Dec., 1903) has demonstrated its existence on the hands of between five and ten per cent. of persons examined indiscriminately. Despite this ubiquitous prevalence of the germ, it has on investigation seldom been found in the normal urethra, or in that channel when diseased. It cannot, therefore, be counted as one of the common bacteria of the urethra. Moreover, statistics show that the *Bacillus coli* is the infecting agent in most of the cases of bacteriuria, whereas staphylococci are comparatively seldom present. We would expect the reverse to be the case, if the infection of the urine were from the urethra, since the staphylococcus is a common, and the *Bacillus coli* a rare, resident of that channel.

Barlow inclines to the belief that the infection often takes place from the bowel by means of lesions of the rectum, citing as causes such factors as fissures or lacerations of the anus, fistula in ano, and even severe massage of the prostate and seminal vesicles through the rectum.

Posner is in favor of the intestine in preference to the blood as the source of infection. In fact, it is only in certain rare cases, where local causes seem entirely lacking, that it becomes necessary to adopt the explanation of Rovsing, that the germs find their way into the bladder through the medium of the circulation.

Even more necessary to explain than the source of the infection is its seat. The bacteria certainly do not live only in the bladder, or the difficulty of removing the condition would be much less than experience proves it to be.

It is difficult to account for the retention of these organisms in the bladder in immense numbers for months and years without exciting inflammation. This may be explained by the fact that the *Bacillus coli* is not, under ordinary cir-

cumstances, a urea-decomposing bacteria, and consequently, as believed by Rovsing, it is innocuous to the bladder as long as free drainage is maintained. This germ, however, it is well known, differs greatly in virulence according to the source whence it comes, and it may be that there is some factor in its environment in the bladder which renders it to a large extent harmless to the tissues. The element which suffices to protect the bladder against infection is no doubt the periodic and complete emptying of its contents by micturition, so that the vesical epithelium is not subjected to prolonged contact with the bacteria. In cases where free drainage is interfered with, as, for instance in prostatic hypertrophy, cystitis speedily results.

In many instances bacteriuria gives rise to no local or constitutional symptoms. As a rule, however, it is accompanied by a peculiar urethral discharge, which may be more or less constant, or only present after efforts at defecation. This discharge may be continuous with gonorrheal flux, which has persisted for an undue period and gradually lost its specific character. Quite as frequently a decided and even considerable interval may elapse between cessation of the urethritis discharge and the appearance of that due to the bacteriuria. An important point is that this pseudo-gonorrhea resists all the usual means of urethral treatment.

In three instances of bacteriuria under the writer's observation, slight nocturnal and diurnal incontinence existed. If the infection is localized in the prostatic apparatus, the urine may present only intermittent cloudiness. Under such circumstances the first portion of the urine will be more or less clear, the second half being lactescent, or it may be only at the end of micturition, when there is energetic contraction of the periprostatic muscular fibers, that the urine shows the characteristic turbidity. In the experience of the writer, the bacterial cloud in the urine may be greatly intensified by "stripping" the prostate and vesicles by means of the finger introduced into the rectum.

Irregular constitutional symptoms may develop during the course of a bacteriuria. Digestive and nervous disturbances, lassitude and intermittent pyrexia are frequent. The occurrence of fever in these cases may be explained on the hypothesis of Boyer and Guinard, that so long as the epithelium continues in a healthy state the toxins produced by the bacteria while in the bladder are not absorbed, but if the toxins from any cause such as deficient drainage become concentrated, the epithelial cells being kept in contact with noxious substances lose their vitality, and absorption takes place, with resulting systemic reaction. Under such circumstances acute symptoms may arise which may even closely simulate typhoid fever, giving, however, no Widal reaction, but showing many coli bacilli in the urine.

The diagnosis of bacteriuria rests upon the presence in the freshly voided urine of an opalescent cloud which cannot be removed by acidulation, filtration or sedimentation. The disgusting fetid odor of the urine is characteristic, and under the microscope large numbers of actively motile bacteria are to be seen. In cases in which the prostate or seminals are the seat of the infection, they are found to be tender to palpation, and yield upon pressure a milky fluid which drips from the meatus, and which, if caught upon a glass slide and stained, is found to be a rich bacterial culture, principally of *Bacillus coli commune*.

The prognosis of bacteriuria depends on the nature, seat and severity of the infection. The condition is always obstinate to treatment—seldom is recovery rapid and complete. In proportion to the extent which the prostate and seminal vesicles are infected is the prospect of recovery prejudiced. The cases in which no infection of these organs can be made out are distinctly more favorable. A strong tendency to relapse exists, and must be carefully considered in framing a prognosis.

An important part of the treatment of bacteriuria consists in the improvement of the patient's general condition by hygienic measures, a full generous diet, careful regulation of the emunctories, and the administration of iron and other tonics as they seem indicated. Urotropin (hexamethylene-tetramin) should be given and continued perseveringly in a routine manner, from twenty to forty grains daily being administered, in divided doses.

Local treatment consists in the correction of any local complication which may exist. Urethral stricture, hemorrhoids, rectal fistula and fissure should be searched for and treated when found. Free drainage from the bladder is most important, and if from any cause, such as prostatic hypertrophy, the bladder is imperfectly emptied by natural means, the catheter must be employed as frequently as may be required to relieve symptoms due to retained urine.

The prostate and seminal vesicles should be carefully examined as to size, tenderness and consistency, and the character of the "strippings" from these organs is to be carefully investigated bacteriologically. If the prostatic apparatus is found to be the seat of infection, the greatest benefit will result from local treatment of these organs. Gentle massage of the prostate and stripping of the vesicles by means of the forefinger introduced into the rectum, should be systematically carried out once every four or five days. The greatest gentleness must be employed in performing these manipulations in order to avoid setting up local reaction through traumatism. A clean sigmoid and colon is to be provided for by means of periodic high enemata taken in the knee-chest position.

Local stimulation of the deep urethra by means of silver solutions appears to be of little avail. If the bladder is irritable, or pus leucocytes exist in the urine sediment, lavage of the bladder, with mild antiseptic solutions, is indicated.

THE USES OF X-RAY IN MEDICINE AND SURGERY.[1]

BY RUSSELL H. BOGGS, M.D.,
OF PITTSBURG, PA.

THE X-ray has two very important places in medicine and surgery, first as a diagnostic agent, and secondly as a therapeutic agent. At present I believe it is generally accepted that the therapeutic uses of the X-ray even exceed those of the diagnostic.

In this paper I will not mention technic any further than to say that it is just as essential that the X-ray operator should have mastered the minor details and be as accurate as a surgeon operating, or a physician prescribing the most powerful drugs.

I have been interested in the X-ray almost ever since its discovery, and during this time have visited many of the American and European hospitals. When I saw that a physician's work excelled along some lines, I inquired carefully into his technic and found his results due to accuracy and other details.

When the X-ray was discovered many physicians placed a machine in their offices and thought all they had to do was to turn on the switch and make a diagnosis without even being familiar with the apparatus, but it was not long before they found out their mistake and most of them discarded the X-ray as a diagnostic agent. But now, with the improved apparatus and better technic, you all know what can be accomplished.

The same is true of radiotheraphy. When a few cases of carcinoma and lupus were reported cured it was natural for many to place machines in their offices for therapeutic purposes, and a large proportion of these have never made it a study and perhaps have only used the rays in a certain line of cases. Then the physician when he would see it recommended by someone for a different disease would treat the first two or three cases that came without first making a study of the technic used by the operator.

As a rule, the physician reporting cases does not give much of his technic, and then when results are not obtained, the X-ray is blamed and not the operator's methods. When we are not able to produce the same results that are reported by another, we should consider first the degree to which the tissues are involved, and our technic, and the way I have been doing it is to visit the physician and learn more about his methods, instead of condemning the treatment.

It is natural that there is a greater difference in the methods of treatment used by the various radiotherapeutists than any other class of physicians, due to the short time radiotherapy has been employed. A surgeon does not condemn intestinal anastomosis because he is unable to perform the operation. A knowledge of the X-ray cannot be obtained in a week or two. I do not believe there is another specialty which requires more careful and hard study than radiotherapy.

The X-ray tube can give a light that will only travel several inches from the tube, or it can give a light that will fluoresce on a screen and show the bones of the hand 175 feet from the apparatus. These rays seem to have a different place therapeutically, the rays from the low tube are very active and have a more destructive action on the tissue, while those given off the higher tube are more stimulating. Every high tube gives off both kinds of rays, and might be compared to a shotgun prescription, as ordinarily used.

Freund states that "it is very likely, just as white light is composed of several colors, Roentgen rays may be composed of various kinds, which may differ from each other in penetrative power as in their physical and physiological effects." The quality as well as the quantity is likely accountable for the results of different operators.

In speaking of the cases which come under X-ray therapy I will classify them under four heads:

1. Those cases which respond readily and as a rule do not need surgical interference; viz., lupus, epithelioma of the face, acne, eczema and tuberculous glands.

2. Those which should be treated for a short time, the mass removed and then continue X-ray treatment to prevent recurrence, viz., carcinoma.

3. Those cases of carcinoma which are considered inoperable should be treated to prolong the patient's life and make him more comfortable.

4. Tuberculosis. Many of these cases in the initial stage respond to X-ray treatment. But here the X-ray should only be considered a useful adjunct.

The treatment of certain skin diseases, namely, lupus, acne, chronic eczema, etc., has reached a stage where it is recognized by many of the leading authorities, as the most effective treatment. However, in the treatment of many skin diseases, it is better to use Finsen light or high electricity in connection with the X-ray.

In this connection I will report a case of acne. Miss B., aged twenty-five years, had acne for ten years, and during this time had been under treatment almost continually. The X-ray treatment was given until some dermatitis was produced and then high-frequency electricity from an Oudin resonator, using a high vacuum electrode, was given. The treatment lasted three months, when the acne had entirely disappeared. I have treated several cases over a year ago, and so far there has been no recurrence of acne, where the treatment was continued for sufficient length of time.

It has been continually said that mammary carcinoma should have postoperative treatment with the X-ray in order to prevent recurrence. This is certainly true, but I believe in certain cases it is more important to treat the case a short time previous to the operation and more particularly so if there is considerable glandular involvement. The disease in the axillary glands can usually be cured in four to six weeks, then the

[1] Read before the Indiana County Medical Society.

mass removed by the surgeon and it will not be necessary to remove the glands.

I have thus treated four cases with excellent results. Also, I have been inquiring from other physicians who are using the X-ray, and many of them say this would coincide with their experience. Now, I do not advocate the surgeon leaving diseased tissue, even if it is necessary to remove all the glands after the X-ray treatment given previously to the removal of the breast.

The other day I had a case referred for an opinion, as I have had many times in the past, to ascertain whether it was an X-ray case or whether it should be treated surgically and then receive X-ray treatment. This case, like many others when they came to the surgeon, had axillary involvement, and one of the glands was as large as a hickory nut. Now, it is reasonable when the glands in the axilla are of this size and the cervical glands are slightly affected, that there is likely to be some involvement of the mediastinal glands, and if the breast, muscles and all the glands are removed, as most surgeons will say at once, will there not likely be a recurrence within six months?

In the last three years I have had referred to me over 20 cases of recurrent carcinoma of the breast. The external signs of the disease in many cases disappeared within from six to twelve weeks, and still in many of these cases the process only retarded, that is, they are cured as far as the external signs of the disease are concerned, but there is often sufficient involvement of the mediastinal and bronchial glands to kill the patient in course of time before coming for treatment. However, the process may be retarded for months. To prove that the X-ray had nothing to do with the involvement of the mediastinal and bronchial glands, I have taken radiographs of the patient's chest at the beginning, and showed these glands to be involved.

I understand that many dermatologists who are not having their cases of epithelioma treated with the X-ray in order to prevent recurrence, use an arsenical paste after the operation to go further into the tissues and destroy the particles which they say are nearly always left. So it seems after careful consideration that every patient should have the benefit of the X-ray when carcinoma is to be treated.

The combination of operation and X-ray gives the patient all the benefits derived from the two best methods. There is no need for delay after the operation in giving a few treatments, but while these treatments should be given in fair doses it is not advisable to continue raying to a point where it will injure the healthy tissues. However, it is a well-known fact that the healthy tissues do not burn as readily as the cancerous. Therefore, it is very important to select the proper dose for each case. It is certainly advisable in treating inoperable cases not to crowd the treatment with the idea of effecting a cure at least in a short time, as by so doing you will break down tissue, and the system will be flooded with toxins with which it will be unable to cope.

This is one of the reasons why some few have opposed the treatment in favorable cases.

In this connection I will report several cases:

Case I.—Mrs. B., aged thirty-eight years, was referred for X-ray treatment on account of the severity of the cancerous condition of the breast. The glands in the axilla were involved extensively, the cancer in the breast had begun to break down, and there was some discharge. The case was treated daily with X-ray for three weeks, when considerable dermatitis was produced. The discharge was checked, the mass in the breast was reduced in size, and the enlarged glands in the axilla had almost entirely disappeared when the patient was operated upon by Doctor Farree, six weeks after the first X-ray treatment. The doctor said he could see that the effects of the X-ray extended deeply into the tissues. Microscopical examinations confirmed the diagnosis. The patient was given a few postoperative treatments and made a good recovery. It is now eighteen months since the operation and there is no sign of recurrence.

Case II.—Mrs. J., aged forty-three years, had a cancerous mass in the breast and some axillary involvement when she started the X-ray treatment by a physician in another city. When she came to my office I advised a removal of the mass and then continue the X-ray treatment. This was done, but after the operation she took only twelve X-ray treatments. It is now a year since the last treatment was given. The patient has had no recurrence, and from the nature of the case a recurrence was expected. I report this case to show the effect of treatment given before operation.

Case III.—Mrs. B., aged fifty years, had extensive involvement of carcinoma in the breast and some little glandular involvement. I had the opportunity of examining this patient before she was operated upon, as her physician wanted the X-ray used afterward. Three weeks after the operation she came for X-ray treatment and at that time her arm was considerably swollen and her shortness of breath and slight cough showed that she had mediastinal involvement. Previous to the operation the arm was not swollen, nor had she any tendency to cough, she had always been entirely healthy. The patient has been treated six weeks with the X-ray and has improved somewhat, the cough has almost disappeared, and the arm is not swollen nearly so much. In this case I do not expect a cure, but only to prolong the patient's life. From what I have seen in my own work, and also in cases which have been related by other men, I believe this patient would have made a recovery, or at least would not have had any swelling of the arm if she had been treated a short time before the operation, as here the physical condition was better than in either of the preceding cases. This is a point to be considered in the treatment of carcinomatous growths.

Case IV.—Mrs. B., aged thirty-five years, had been operated upon for carcinoma of the breast

six months before she had a recurrence. The breast, muscles and glands had been removed. When she came for X-ray treatment there was considerable involvement of the tissues of the chest walls. Treatment was given every day for ten days, afterward three times a week for a period of two months, when all the external signs of the diseases had disappeared. When she came I took a radiograph of the chest, which shows the mediastinal and bronchial glands were involved. The treatment will prolong her life, but it can hardly effect a permanent cure.

Hyde, Montgomery and Ormsby, in the *Journal of the American Association,* in speaking of epithelioma, say: "Of fifty-five cases of carcinoma of the skin treated by us with radiotheraphy, the majority were of the superficial type, known generally as epithelioma or rodent ulcer. The value of the X-ray in the removal of such growths is so generally recognized that we shall give here a summary of our observations, together with a brief outline of a few typical and otherwise interesting cases. In the superficial form of carcinoma our results have been quite uniformly successful."

I believe this report of Drs. Hyde, Montgomery and Ormsby will coincide with the reports of a large number who are employing the X-ray. However, I do not believe it is wise to continue the X-ray treatment of epithelioma for more than six weeks, unless considerable improvement has taken place; then diseased tissue should be removed at once. But, I believe that cases that have not responded to X-ray treatment in most cases have been treated by a tube which was too high in vacuum. I know of such a case which had been treated for some time and no results produced. The patient went to another operator who used an extremely low tube, and six treatments in two weeks produced the desired amount of irritation, and within four weeks the epithelioma had entirely disappeared.

MEDICAL PROGRESS.

MEDICINE.

Etiology of Pneumonia.—The examination of healthy lungs have convinced H. DÜRCK (*Münch. med. Woch.,* June 28, 1904) that a large number of bacteria, including the pneumococcus, are almost constantly present in the alveolar spaces. In certain animals the filtering apparatus of the upper air-pasages is very perfect, but in man even coarser particles reach the lung and give rise to the well-known discoloration. Another factor thus must be active to set up an inflammation, and this the author believes to be sudden exposure to cold. If a pure culture of pneumococci is blown into the lungs of animals nothing will usually happen, but if the animals are first chilled by placing in ice-water, a pneumonia results almost invariably. Autopsy shows a typical lobar consolidation.

Excretion of Iodine with Iodipin.—The greatest disadvantage of administering iodides is the rapid excretion, so that fairly large amounts must be given in frequently repeated doses, with the result that iodism is common. The excretion begins in half to several minutes and ceases in about thirty-six hours after one gram, after about 80 per cent. has passed into the urine with iodipin. H. SINGER (*Zeitsch. f. klin. Med.,* Vol. 52, Nos. 5 and 6) found only about 60 per cent. in the urine and the excretion was continued over four to five days. With rest and abundant food the excretion is slower than if the patient is active and insufficiently fed. As with the iodides the largest amount of iodine is found in the urine directly after injection, but the excretion has a tendency to be more uniform.

Infusions in Pulmonary Tuberculosis.—A very extensive research on this subject has been made and is now published by JACOB, BONGERT and ROSENBERG (*Deut. med. Woch.,* No. 28, 1904). Their study is both experimental and clinical and the technic of their method as applied to the human subject is as follows: The laryngeal surface of the epiglottis and the vocal cords is anesthetized with a 20 per cent. cocaine solution. Shortly after a thin tracheal rubber spray tube is introduced through the glottis and through it the trachea is sprayed with several c.c. of a 2½ per cent. solution of β-eucaine. The coughing which is apt to follow does not usually last very long. A bougie, provided with a very flexible stilet, is then introduced into the trachea. When this is in place the stilet is removed and the bougie may then be carefully pushed down into either bronchus. A syringe containing the tuberculin is attached to the bougie and the fluid slowly injected. The amount was usually about 20 to 30 c.c. of a solution of 0.01 to 0.02 of the tuberculin to 100 of water. As the reaction to the tuberculin disappears, the quantity of tuberculin is increased. After treatment, the patients are put into the horizontal position, as it was found that in this way the fluid found its way into the upper parts of the lung. The authors claim that after a little experience this procedure can be completed in about ten minutes, and is well borne by the patient. The method was applied in five cases, all of which were in poor general condition and in the second stage of the disease. The infusions varied in number—in one 38 were given in the course of four and a half months; in another 18 in two and a half months. The results are reported to have been excellent and the patients were considered to have been clinically cured,—the physical signs having disappeared, symptoms being relieved and an increase in weight noted. The method was apparently harmless, as no unpleasant after-effects were noted. It is also claimed that the procedure will have a diagnostic, in addition to its therapeutic value. It was found that if an individual was afflicted with tuberculosis, the injection of the tuberculin, as described, will be followed by a reaction if only 1-10 or 1-12 of the dose is given which would be necessary in order to obtain a reaction by the subcutaneous method. If the tuberculous process is localized in some other part of the body than the lungs, the reaction after the infusion will only appear after an equal or greater dose has been injected than would be required for subcutaneous injection. A special monograph is about to be published by the authors, which will contain a more detailed description of their researches.

SURGERY.

Congenital Elevation of the Scapula.—An interesting contribution to the etiology of this subject is contributed by H. J. LAMERIS (*Archiv f. klin. Chir.,* Vol. 73, No. 2), who reports in detail a case where examination disclosed a tense band extending from the angle of the scapula to the tip of the fourth spinous process. An operation showed that the band was a portion of the lower segment of the rhomboideus muscle which had undergone connective tissue changes and become con-

tracted. After extirpation of the band, the deformity partially disappeared and the motion of the arm was less interfered with. The author believes that some lesion of the rhomboideus muscle was the cause of the scapular elevation in his case, and he considers the condition analogous to that seen in the sternomastoid in congenital wryneck. Similar observations made by Sainton, Kirmisson and Roger, seem to show that a lesion of this nature in the rhomboideus muscle plays a very important part in the production of scapular elevation. The variety of positions assumed by the scapula in this condition can be explained by assuming that a contraction of either the upper or the lower part of the muscle pulls the bone in one direction or the other. The diminished rotation of the scapula can also be explained by the same reasoning.

Subcutaneous Alimentation.—Artificial methods of giving nourishment subcutaneously is discussed by P. L. Friedrich (*Archiv f. klin. Chir.*, Vol. 73, No. 2). This method has been advanced as of particular value in abdominal surgery and the author has used it with success in several cases of peritonitis, gastric and intestinal perforation. He used the preparation devised by Prof. Siegfried, designated as pepsin-fibrin-pepton, which may be readily sterilized and remains so for several weeks. The maximum dose is about 20 gms. daily. He has employed it from ten to fourteen days and succeeded in tiding these patients over until nutriment could be given by other channels.

Tuberculosis and Osteomyelitis of the Patella.—This condition is exceedingly rare, for among the large number of surgical cases at the clinic in Jena during the past fifteen years, W. Ropke (*Archiv f. klin. Chir.*, Vol. 73, No. 2), reports only eight cases of primary tuberculosis and two cases of osteomyelitis of the patella. Young persons seemed to be the most often affected. The diagnosis of a suppurating or a tuberculous focus in the patella depends on the localization of the focus and the involvement of the joint and the overlying soft parts. As soon as the diagnosis of either condition is made operative interference is imperative on account of the danger to the joint. This may become anchylosed or secondarily affected with tuberculosis. If perforation of an osteomyelitic focus has already taken place into the joint, and a suppurative arthritis resulted, the focus in the patella must be thoroughly cleaned out and the joint punctured and drained. It may thus be possible to obtain more or less mobility in the joint. If the tuberculous process in the patella is combined with a similar one in the knee-joint, and a resection of the latter is done, the question as to what disposition is to be made of the patella depends on the extent of the lesion in this bone. It may be either totally extirpated or retained for the purpose of filling up bony defects in the femur or the tibia, which have resulted from the excision of diseased bone.

Soap Tinctures for Cleansing the Hands.—An interesting article on this all-important subject is presented by R. Falck (*Archiv f. Chir.*, Vol. 73, No. 2). His experiments have been made with the spores of molds. These spores may be divided into two types which behave differently toward antiseptics. The one variety is coated with a film of air which defies all watery solutions, but is readily susceptible to strong alcohol, and the underlying spore is quickly killed. The other variety has a mucous or gelatin coating, which resists alcohol in the dry state, but is readily affected by watery germicidal solutions. The writer believes that a similar condition applies to bacteria and that a combination of the alcohol and watery germicidal solution is necessary to produce complete disinfection of the skin. The latter process must be based on a combination of mechanical cleansing with chemical disinfection. The first part should consist of the application of an alcoholic solution of soap, as this will penetrate deeper into the skin than the watery solution. The alcohol, however, must not be too concentrated, otherwise a contraction and hardening of the epidermis results, which renders it impervious to the action of the soap. An alcoholic soap solution, moreover, removes the air and emulsifies the fats, in this manner bringing the germs in the skin into the field. In addition those spores are moistened, which resist to a greater or less degree the action of water, and are then destroyed. The remaining spores are also rendered more susceptible to the action of the succeeding watery solutions. These indications have been met by the author in a soap which on the addition of water forms a "tincture" of the following composition: Soda soap, 15 per cent.; water, 15 per cent.; alcohol, 70 per cent. The process of washing the skin is divided into three parts: (1) The soap is softened with a little water and rubbed thoroughly into the skin; (2) this is rubbed up into a foam with water; (3) after rinsing, disinfection with lysol or corrosive sublimate. The author has had good results with this method, especially in getting rid of the spores of molds.

Newer Methods of Opening and Closing the Abdomen.—There is no more remarkable fact in surgery of the present day than the want of unanimity existing as to the best method of opening and closing the abdomen in abdominal operations for pelvic diseases, remarks E. Hastings Tweedy (*Brit. Jour. of Obst.*, June, 1904). The vertical incision is still the operation of choice among British surgeons, but upon the continent the transverse incision has largely superseded it. In the transverse incision, a slight curve is made with the convexity toward the pubis and through the skin, adipose tissue and sheaths of the recti. The structures are raised as a thick flap above and below the incision, from the muscles lying below them. The divisions between the recti can now be clearly made out; the latter are separated and the abdomen opened in the usual manner. The advantages of such an incision are manifest. In the first place, it runs in the direction of the elastic fibers of the skin; as a rule the parts fall naturally into position on the completion of the operation, and the fear of hernia is reduced to a minimum, the severed aponeurosis is, throughout the greater part of its course, protected by the muscles, and it is only the transverse slit extending between these, that could by any possibility, permit of the escape of the abdominal contents. The application of a few interrupted sutures, superficially placed in the muscles, sufficient to keep them in apposition until adhesions form between them and the overlying fascia, will eventually prevent the occurrence of hernia. The scar left after such a wound has no tendency to spread. The prevention of hernia is entirely dependent upon the proper technic, which is followed in the closure of the abdominal wound, the main objects of which should be strict asepsis, careful apposition of the more important abdominal layers, and lastly, the prevention of subcutaneous hemorrhage. It is a safe precaution to close off the peritoneum by means of a continuous suture of fine silk. To keep the muscles in close apposition their external sheaths should be sutured, which the author formerly did after the method of Howard Kelly, but now a continuous layer of silk is employed, as it can be more rapidly introduced. In the closure of the skin wound, a subcutaneous suture of silkworm gut is placed in the usual manner and either end is threaded through a thin lead plate which is placed over the long axis of the wound. Aseptic dressings are

placed over the plate and an abdominal binder is applied in the usual manner, the parts being left undisturbed for fourteen days. The plate affords a ready means of preventing the cuture slacking, and does not permit the wound to pucker. The author is convinced that the lead itself exercises a favorable influence on the healing process, for otherwise it would be difficult to account for the perfection of the scar.

Clamp and Cautery in Appendectomy.—The abscission of the appendix and disposition of the stump are the two most important steps in appendectomy. The method probably employed by most surgeons is to ligate the meso-appendix and neck of appendix, invaginate the stump into the cecum after treating it with some antiseptic, and secure it by a pursestring or Lembert sutures. Another much-used method consists in turning down a cuff of peritoneum, pulling up the other coats and ligating these at the base, abscissing, permitting the stump to retract and suturing the peritoneal cuff over the stump. J. R. EASTMAN (*Am. Jour. Obst.*, July, 1904), calls attention to objections attendant upon both of these methods.. A circular ligature about the base of the appendix, either internal or external to the serosa, does not permit of exploration to determine the patulency of the canal of the stump. Should such a ligature be placed beyond a stricture, conditions are established favorable to a fresh attack of inflammation. Some surgeons do not apply an external circular ligature, but cut the appendix, compress the proximal end, and after sounding the canal, invaginate, securing the stump with Lembert or pursestring sutures. This method is especially dangerous when the tissues are thickened or friable, or, if there is extensive suppuration, for in such conditions there is great likelihood of escape of the contents of the appendix or cecum. The writer advocates the use of a light clamp with broad accurately-fitting shields to be applied to the base of the appendix close to the cecum. Such an arrangement would preclude the possibility of pus from the appendix or cecal wall contaminating the neighboring serosa or floating into the peritoneal cavity. The appendix should then be severed with the cautery just above the clamp, the shields protecting the neighboring structures from the heat. Whatever fluid contents that might have escaped, will have been rendered sterile by the cautery. When the shields and clamp have been removed, a thin seared edge remains which may readily be invaginated. Additional advantages claimed for this method are, that the shields hold back coils of intestines, hemorrhage is minimized and the time of operation materially shortened.

NEUROLOGY AND PSYCHIATRY.

Examination of the Cerebrospinal Fluid in Nervous Diseases.—In order to determine the value of these examinations in the diagnosis, E. SIEMERLING (*Berl. klin. Woch.*, May 23, 1904) has made an extensive series of observations, in which not only the histological characters, but also the physical and chemical properties of the fluid were considered. Lymphocytosis, when taken in connection with other symptoms, has usually been considered as indicative of meningeal irritation. Thirty-eight cases of progressive paralysis examined showed a lmyphocytosis in all but one. It may, therefore, be considered as one of the early symptoms. In epilepsy and simple melancholia, negative results were obtained. In all cases of organic and nervous diseases, a well-marked leucocytosis was present, but was absent in pure neuroses and apoplectic dementia. In a case of extradural hemorrhage, the red color seen in the specimen of cerebrospinal fluid remained after the specimen was centrifuged. In another instance where the bleeding took place into and broke through the floor of the third ventricle, the fluid remained clear after the blood had settled to the bottom of the tube.

Polyneuritis and Landry's Paralysis Following Influenza.—E. BRACCHI, in *Gazz. deg. osped.* (June 26, 1904), says that the modern conception of intoxication, whether bacterial or biochemical, to which the nervous system is especially susceptible, has assumed a definite form, namely, as a polyneuritis or an ascending paralysis. Acute infectious diseases conquer the most variable nervous disorders, both in symptoms and location of lesion, the commonest and one of the most serious in its results is influenza. Two cases of Landry's paralysis show new evidence of the toxic nature of influenza, as well as a contribution to the rare complications of influenza. Case I.—A child, aged nine years, suffered from influenza in 1899, recovered, but shortly after developed a paraplegia, and next an ascending paralysis of the trunk and arms, the paralysis being flaccid. Next bulbar, respiratory and cardiac symptoms appeared. The third nerve was paralyzed. Normal cutaneous sensibility was present, except for some paresthesia and delayed sensation. The tendon reflexes progressively disappeared. The sphincters are normal, the temperature not much elevated. Twenty-five days from the onset the symptoms began to disappear in the inverse order of their invasion, leaving great weakness and muscular flaccidity. No trophic disturbance appeared at any time. Complete recovery came after eight months. The second case, a child of two years, suffered from a descending form of Landry's paralysis, occurring during the influenza epidemic of 1899. The child developed a gastro-intestinal type of influenza, and some days later difficulty of swallowing and rapid respiration developed, saliva accumulated in the mouth, and the lips and palate were partially paralyzed. Next the arms became paralyzed, then the trunk and legs. The cranial nerves did not present noteworthy symptoms. The reflexes were absent, sphincters intact, electric reaction unaltered, the skin sensibility was normal, there was marked cyanosis. After fifteen days the bulbar symptoms increased and the patient died of respiratory paralysis. The third case was polyneuritis in a man, about fifty years old, following influenza. In conclusion, the writer notes the predilection of the toxin of influenza to attack the nervous system, even a long time after the acute symptoms have passed. Landry's paralysis has been noticed after typhoid, tuberculosis, syphilis, puerperal fever and measles.

Brachial Neuritis.—This very important topic has been accorded scant courtesy in most of the text-books. CHARLES W. BUCKLEY (*Lancet*, April 16, 1904) states that, aside from injury, gout is undoubtedly the most important etiological factor in producing this symptom. In men the neuritis is often accompanied by the ordinary manifestations of gout, whereas in women, these are apt to be irregular and difficult of recognition. Duplay records the following changes in the joint: (1) Chronic subacromial bursitis and subdeltoid cellulitis with obliteration of the bursa and formation of adhesion between the deltoid and the humerus: (2) chronic inflammation of the capsule leading to thickening; (3) periarticular cellulitis internal to the joint leading to formation of fibrous tissue; (4) congestion of the ulna and internal cutaneous nerves; (5) atrophy of the deltoid. Weir Mitchell says any form of nerve lesion is capable of developing in the joints inflammatory conditions, usually subacute, which so precisely resemble rheumatoid arthritis that no clinical skill can distinguish between the two. The prominent symptoms are pain which varies in

degree, but which may be very severe; tenderness to the affected nerve trunks and of certain cutaneous areas related to them; weakness of certain muscles and limitation of movement; trophic changes, rarely severe and sensory changes, anesthesia and hyperesthesia which often persist after the other symptoms have disappeared. The diagnosis from angina may be very difficult. Aneurism again is a possible source of error and tumors of the cervical spine or of the bones and shoulders may cause pressure on the nerves so as to closely simulate neuritis. Prognosis is variable, the duration being probably never less than three or four months, and disability may extend over a year or more. The older the patient the more difficult the case. Recovery dpends largely on the amount of rest obtained. Young people recover more readily than old. Relapses are not infrequent. A sling is occasionally useful, but much better results are obtained by bandaging the affected limb to the side. As most of the cases are of gouty origin, they should almost be put on antigout treatment. Free blistering along the infected nerve trunks is often very serviceable and galvanism may be a valuable aid in the mitigation of pain. Massage is positively contraindicated as long as there is any acute inflammation.

Uremic Aphasia.—The history of paralysis due to uremia is comparatively recent. Lesegue denied it. Trousseau considered it probable. Lancereaux was the first who in 1875 admitted the possibility. Brunet in 1893 published a clinical observation of uremic aphasia. In 1894 Dufré reported ten such cases. Breton (*Gazetta degli ospedali*, April 12, 1904) reports a case of a man of forty years who in the course of Bright's disease, albuminuria 5 grains to 1,000, was taken by a short attack of incomplete paralysis of the right arm and leg. Motor aphasia, without word deafness, word blindness, nor amnesic aphasia was present. The patient, understanding all that was said to him, and showing no mental confusion. Agraphia was present, but only of the paralyzed arms, as the patient could pick out letters of the alphabet to express his thought. The paralysis improved, but the aphasia persisted. The albuminuria disappeared. In literature uremic aphasia has been described as intermittent, as in other toxic aphasias, and benign, and it was said that it would not persist even in fatal hemiplegias. In the experience of Breton, it is not unusual for the paralyzed limbs to rapidly regain their function, but the aphasia remains invariable unto death. Usually uremic aphasia is accompanied by agraphia and word blindness. Localized edema of the brain, cerebral atheroma and local congestion may be present, caused by the toxic urinary products or ptomains.

Disseminated Sclerosis Simulating Spastic Paraplegia.—Notwithstanding the fact that disseminated sclerosis is by no means a disease of infrequent occurrence, its diagnosis is at times quite difficult, the more so, as we seldom come across typical cases as described in the text-books. Pathologically the disease presents disseminated foci of sclerosed tissue in the brain and spinal cord, and there are no two cases that would, to any considerable extent, resemble each other. The etiology of the affection is uncertain; syphilis does not seem to play any part in it; more importance is attached to infectious diseases, especially smallpox and typhoid fever. The classical case, according to the French school, presents the following array of symptoms: Weakness in the lower limbs, tremor and attacks of dizziness; objectively muscular weakness in connection with rigidity of the lower limbs, increase of tendon reflexes, spastic-paretic gait, intention tremor, nystagmus, the well scanning speech, and finally apoplectic attacks, eventuating in monopolegia. The case of R. A. Fränkel (*Prakt. Vrach*, No. 23, 1904), is rather atypical, inasmuch as the patient, a man of twenty-seven years, single, complained first of difficulty in walking, especially with his left leg, which has kept on the increase for the last two years. The patient gave a negative anamnesis as regards his family, while he himself underwent an attack of diphtheria when eight years of age, and later on passed through a severe attack of malaria, as evidenced from the enlarged spleen on palpation. The patient exhibits a typical spastic gait with the characteristic "gluing" of the toes to the floor; intention tremor in left arm and leg, no muscular atrophy, tendon reflexes very much exaggerated, bladder and rectum functionating normally, otherwise in symptoms mentally sound. At the expiration of three weeks after this examination patient again presented himself with a history of two severe attacks of dizziness accompanied by loss of consciousness of some hours' duration. There could then be no more doubts of the diagnosis of disseminated sclerosis, which had evidently first invaded the pyramidal tract of the lateral column, thus giving rise to symptoms simulating those of spastic paraplegia. The author inclines to malaria by the etiological factor in the given case.

Erythromelalgia.—The case as related by A. M. Virshufsky (*Prakt. Vrach*, Nos. 21 and 22, 1904), is that of a man who, since his twentieth year, when he had passed through an attack of scarlet fever, has been suffering from attacks of pain and pruritus around both wrists followed by the appearance here and there of red spots of various sizes; this redness disappears under pressure, but reappears as soon as the pressure is removed; with this there is also swelling of the hands and fingers; the attack eventuates in sweating of the parts. The same phenomenon is observed around the ankle-joint, but to a less marked extent. The attack lasts for a few hours at intervals of several hours and sometimes of days or even weeks. The patient is otherwise perfectly healthy, and does not feel very bad even during the attacks, obtaining considerable relief by immersing the affected parts in warm water. The patient had subjected himself to various sorts of treatment but without any relief. His anamnesis leads the author to exclude alcohol and syphilis. The group of acroparesthesias is excluded in this case as the attack is not characterized by either anesthesia or hyperesthesia, nor any other disturbances of temperature. The author also excludes tarsalgia, podalgia, as well as the so-called alkinesia algera of Möbius. As the patient is but twenty-one years of age arteriosclerosis is excluded as the causative agency of the affection. Among the skin troubles that may simulate the disease under consideration of erythema exsudatium multiforme and erythrodermia (Pick, Kaposi and others) are mentioned by the author, but must be excluded for the lack of some symptom or other. Thus it remains to group the disease, the chief features of which are erythema, pain, edema, sweating and trophic disturbances (urticaria) all occurring in paroxysms and on symmetrically disposed localities,—as the angiotropho-neurosis described by W. S. Mitchell in 1878 as erythromelalgia. The disease is very rare (possibly not recognized?), as is evidenced from the fact that Oppenheim, notwithstanding his very extensive clinical experience, mentions but two cases seen by him. In the majority of the cases described erythromelalgia was met with either as complicating a general neurosis, or as a local manifestation of some organic disease of the nervous system (myelitis, tumors, gliosis spinalis, etc.), or again as a symptom of a peripheral disease of the nervous

system, and finally as a manifestation of arteriosclerosis. As causative agencies of the disease have been mentioned extreme fatigue of the extremities, climatic influences, rheumatism, preceding infectious diseases and so on. The author is inclined to consider the affection as due to scarlatina in his case. According to Senator the disease is pathologically an active hyperemia of the vessels resulting from paralysis of the vasoconstrictors or spasm of the vasodilators; while the symmetry of the affected parts leads him to consider it as a disease of the central nervous system. Eulenberg localizes the affection to the gray matter of the brain, in its posterior and lateral portions, and considers the symptoms of erythromelalgia as due to dynamic functional alterations of the corresponding ganglia resulting from their exhaustion or pathological condition. As regards treatment, little, indeed, can be effected. The patient (apropos, a pharmacist by profession) tried arsenic, pyramidon, ergotin, salicylate preparations, belladonna, antifebrin, of which the last brought some relief for a few days only. Various hydrotherapeutic procedures are recommended, such as general or local baths, douches, salt water, compresses, as well as local faradic baths; The author considers the last as of some value. Operative interference (as resection of the ulnar, posterior tibial nerves, etc.) seems to have benefited some cases.

OBSTETRICS AND GYNECOLOGY.

Torsion of the Fallopian Tube.—It has fallen to the lot of most men who have operated on a considerable number of various tumors to come across an ovarian cyst with twisted pedicle, associated with hematosalpinx, produced by the torsion of a hydrosalpinx which was adherent to the ovarian cyst. Mr. Bland Sutton, according to HAMILTON BELL (*Brit. Jour. of Obst.*, June, 1904), was the first to record such a case and this in 1891. There is no single exciting cause in the production of this condition, but the presence of a solid tumor on a dermoid has been frequently noted. Here there must be a fairly long pedicle and a smooth peritoneum, free from all adhesions. Others suggest that the alternate emptying of the rectum and bladder may cause torsion, and this latter might produce a gradual twisting but never an acute strangulation. In most cases of pyosalpinx, the adhesions are numerous, and torsion is therefore impossible. Besides, in hydrosalpinx, there are sevparticularly has insisted on the slow or chronic variety particularly, has insisted on the slow or chronic variety of torsion but it is by no means so common as the acute form. The number of twists varies greatly in the recorded cases, from a half turn (*i.e.*, through 180°) up to 4½ twists. The actual number of twists is really of little importance. The usual tumor of the fallopian tube to undergo torsion is a hydrosalpinx, and it is transformed by the hemorrhage induced by the torsion into a hematosalpinx. Pregnancy does not seem to play an important part as a predisposing agent, as diseases of the tube are commonly associated with sterility, absolute or relative. The most prominent symptom, common to all cases, is abdominal pain, of a severe type, situated in the lower part of the abdomen. The pain is sudden in onset and very sharp, often leading to faintness and even syncope. Sometimes the pain radiates to the inguinal region and legs, to the hypochondrium, or to the loins. This has led to wrong diagnosis, such as appendicitis. There is usually little or no interference with menstruation. Peritonitic symptoms are well marked. Vomiting is commonly noted, of varying severity, but never fecal. Frequency of micturition is occasionally present. The presence of a tumor in the abdomen is very characteristic of this lesion. Vaginal examination is useless, unless the tumor is located in the pouch of Douglas. In the fifty cases reported an absolute diagnosis has never been absolute before operation. There is usually an exploratory operation performed for a tentative diagnosis of salpingitis or appendicitis. The treatment is necessarily surgical, and the abdominal is the correct route to operate by. The prognosis after operation is favorable. So far only three deaths have been recorded from such treatment.

Case of Quintuplets.—For the specimens and history of this most interesting case, G. C. NIJHOFF (*Brit. Jour. of Obst.*, July, 1904), is indebted to Dr. J. J. Blécourt, of Hees, Netherlands. The mother was a healthy, robust woman, aged thirty-four years. Seven years previous to the present conception she had been delivered of a male child. The last menstruation was January 20, 1903. In March there was, for a few days, a slight discharge of yellowish fluid, tinged, at times, with blood. The quickening was first felt early in June. At 8 o'clock P. M., July 12, labor pains began. At that time fetal heart sounds could be heard at both sides and in the middle of the abdomen. The fundus uteri was a hand's breadth above the umbilicus. At 8.30, soon after the rupture of the membranes, an immature, but living, female child was born, followed in ten minutes by a second child (female). Some minutes after the birth of the second child, a new bag of waters was made out. At 9 o'clock a third child, a male, was born, in a vertex presentation, soon followed by a fourth child, a female, in footling presentation, with back anterior. Within a few minutes the fifth child, a female, was spontaneously born in footling presentation. The five children were alive, but immature, and survived only one hour. During the puerperium no untoward symptoms appeared, other than an increase in temperature (37.9 C.) on the third day. Immediately after birth the combined weight of the five children was 3,150 grams. The placenta was single, oval in form, with a transverse diameter, 18.5 CM., and longitudinal diameter of 25 CM. Its thickness varied from 0.4 to 3 CM. Its weight was 890 grams. At its fetal side five separate umbilical cords were inserted, each by a distinct sac formed from the fetal amnion, three of these sacs were enclosed by a common chorion. The two others had a separate chorion. The author thinks that these quintuplets may be regarded as the product of the fecundation of three ova. In the mother's family several cases had occurred of multiple pregnancy. Her mother once had twins among other children. Two maternal uncles became fathers of twins. A maternal aunt was delivered of triplets. There were no cases of multiple births in the father's family.

Significance of Fever During Labor.—The etiology, course and prognosis of fever coming on during labor, have been carefully studied in a series of 200 births in the clinic at Königsberg by E. IHM (*Zeitsch, f. Geb., u. Gyn.*, Vol. 52, No. 1). Primiparæ seemed to be most often affected (43 per cent.). Other etiological factors were narrow pelvis or rigid soft parts, improper position, prolonged duration of the labor, early rupture of the membranes. The prognosis for the puerperium was shown by the following: 41.5 per cent. continued to have a temperature, 8 died (5 of sepsis), 26 developed a severe puerperal fever. The effects on the children were shown by the fact that 36 per cent. died. Therapeutic indications point to measures for the purpose of hastening delivery. For this he suggests hot vaginal douches, dilatation of the cervix by rubber bags or Bossi's instrument, version, forcing the head into the pelvis and applying the forceps, rupture of the membranes. Version he considers a rather dangerous procedure.

SATURDAY, AUGUST 20, 1904.

THE SEGREGATION OF URINE.

THAT this difficult task is one of the most important to deal with accurately, in every case of suspected surgical renal involvement there is not the slightest doubt. If there were, the multiplicity of instruments and methods for establishing this segregation must convince the disbeliever of his fallacy.

Albarran, of Paris, one of the greatest of genito-urinary surgeons, was the first to popularize the catheterization of the ureters. In the male this technic is extremely difficult, calling invariably for the hand of a thoroughly trained expert. Six years ago there were few in New York who could do this catheterization with any degree of certainty or rapidity. To-day, of course, there are a number of men who experience no difficulty in the average case and with the assistance of improved instruments readily pass the ureterovesical valve. Nature's arrangement of this admirable barrier to the outside world speaks trumpet-voiced in disfavor of ureteral catheterization. A technic so thoroughly at variance with her plans and methods for the protection of the organism against invasion from the outside, could have but one ending. Thus it is that ureteral catheterization for the most part has had its day and is passing.

Lambotte, of Brussels, constructed a rude instrument in 1890 which was the precursor of Harris's more perfect device. The segregator which he devised is of extremely ingenious construction. It depends upon the principle that the base of the bladder may be lifted by a tent-like structure, which is introduced into the rectum. This creates two lakes, one on either side of the ridge, each one having a ureteral opening near its center. Moynihan, in an article on intravesical separation of the urine, in the *British Medical Journal*, July 2, 1904, states that while Harris's instrument is most ingenious in construction, in actual working it is found not to be strictly reliable.

In order to gather a sufficient amount of urine for differential purposes, the segregator must remain in place for at least twenty minutes or half an hour,—the period of time being determined by the rate of urinary secretion. Its introduction and its tolerance for this length of time is confessedly annoying and disquieting to the patient.

Moynihan, in his article referred to, pictures the intravesical urinary separator of Cathelin and of Luys. These instruments differ only in the very smallest and most unimportant details, and a description of one will therefore suffice for the two. It consists of three portions, a central one within which lies a chain attached at the handle of the device to a wheel. The instrument is straight until the last two inches are reached, where there is a marked curve, forming almost a semicircle. A screw is so arranged that from the outside one may tighten the chain, whereupon, instead of lying in the hollow of the curve of the instrument, as it does during introduction, it is raised up across the metal semicircle mentioned. Attached to this chain is an india-rubber sheathing. This is lifted by the chain and a septum is thus created.

When it is wished to utilize this instrument, it is passed in the manner of an ordinary sound, and after entering the bladder is withdrawn until the beak is felt to impinge tightly against the pubes. The chain is then tightened and the diaphragm is created. Moynihan states that various sizes of Cathelin's instruments are now made to fit the various-sized bladders which one is sure to encounter even in average-sized adults. The author admits that there is a difficulty in knowing that for a certainty the bladder has been tightly diaphragmed, but he expresses the belief

that a certain amount of tactile education and the use of these various-sized instruments will do away with this possible difficulty.

The opinion of such an extremely able operator as Moynihan must have very great practical weight. His conclusions therefore are quoted as follows: "My present opinion is in favor of the use of Luys's instrument for the female and of Cathelin's for the male, but I am prepared to admit that a more extended experience may modify my opinion. There can be no doubt that both instruments are of great practical value. I propose shortly to publish a complete series of observations, but meanwhile I may call attention to two cases reported by me in the *British Medical Journal,* April 30, 1904, in which great help was given by the separation of the urine."

J. Lynn Thomas (*British Medical Journal,* July 2, 1904), in speaking of the advantage of the Cathelin separator over other methods, particularly in reference to the discomfort caused, states that he left the instrument in a male patient's bladder for one hour and twenty-five minutes with very little discomfort. He says that since the publication of Bickersteth's article, in the *Lancet,* March, 1904, both the Luys and the Cathelin instruments have become well known and are receiving wide attention throughout England. He has found Cathelin's instrument to effect such a perfectly tight division of the bladder, that on introducing water, colored with potassium permanganate on one side, he was able to withdraw clear water, which had been introduced at the same time as the permanganate water from the other side. This showed that there had been absolutely no mixing. Similarly he found in another patient suffering from hematuria, that Cathelin's instrument drew highly colored bloody urine from the right side and clear urine containing albumin from the left. The first was alkaline, the second was acid. He believed at the time that the albumin on the left side might be due to a trace of the right-sided urine leaking past the diaphragm of the instrument. After operation, however, at which he removed a right-sided carcinomatous kidney, the urine became clear, but continued to contain albumin just as it did prior to operation. This shows that there had been no leaking.

At the recent meeting of the American Surgical Association in St. Louis, an instrument very similar to Cathelin's was exhibited. It had been devised two or three years ago by the member who showed it. He stated that he exhibited it simply for the purpose of showing that he had been experimenting along these lines without success. The instrument in his opinion was in no way comparable to the Harris segregator and he advised the members that it was not practical to effect a division of the bladder into two halves with sufficient accuracy to be of clinical importance or use. This opinion was not disputed by any member present, the evident sense of the Association being that it concurred with the opinion expressed by the speaker.

Coming as they do so closely upon each other, these very diverse views on a very pertinent subject of extremely prominent British and American surgeons are interesting and instructive, but it looks at the present moment as though our transatlantic confrères have the best of this argument.

EPIDEMIC CEREBROSPINAL MENINGITIS.

During the last six or eight months New York City and many other places here in the East have suffered from an epidemic of cerebrospinal meningitis, and its lessons should not be allowed to pass unconsidered. The usual mortality from the disease is said to be something over 30 per cent. In the present epidemic at least this high death rate has been reached, and there are some who consider that nearly one in two of the patients who were victims of the genuine epidemic disease succumbed to it. It must not be forgotten, however, that usually in epidemics the disease is more fatal after it has existed for a time and has, as it were, acquired virulence by passing through series of susceptible individuals, and that the mortality has been known to go above 60 per cent. When the reports are all in, the experience may prove sadder than at first anticipated.

When epidemic there is every reason for taking what might seem extreme precautions against the spread of the disease. At the present time it is not known how the affection is communicated. Some reports of development of the disease after the occurrence of injuries of various kinds, especially those inflicted on the street, indicate that the disease may be contracted by contamination with street dirt, as is tetanus. The analogy with tetanus, pursued still further, would not make the limitation of the disease to the central nervous system so surprising. It seems not impossible, however, that in time contact with sufferers from the disease may give opportunity for the spread of the specific micro-organism. It has been often noted in Europe, and we believe also in this country, that the first case of the disease seen in a neighborhood occurred in a

tramp or wanderer. The study of this possible method of transferring the disease might throw great light on the methods of transmission.

The disease is usually said to be associated with filthy or uncleanly surroundings. The part the tramp is supposed to play in the matter of sporadic cases would seem to be in accord with this. There are, however, many cases of the disease reported among the well-to-do, where cleanliness is a constant habit. In the theory of the agency of street dirt in the causation of the disease, it must not, however, be forgotten that while unlike tetanus, the micro-organism seems to be present not constantly, but only at times of epidemics. At such times all wounds that have been contaminated with street dirt require more careful attention than before, even though they may not be severe.

While cerebrospinal meningitis is spoken of as an epidemic disease, and occurs in marked epidemic form about once every decade, it must be remembered that the affection is practically always existent, and that in Germany, where careful studies and analyses of statistics have been made in order to ascertain the course of frequency of the disease, it has been found that in different parts of the country some cases of the disease are always occurring. The same seems to be true here in the United States, for, as was pointed out by Dr. William Browning, in the *Brooklyn Medical Journal* for May, in an article on cerebrospinal meningitis in Brooklyn, some cases of the disease have been occurring at nearly all times during the last ten years. He considers that the germ is widely and continuously present in Brooklyn, and the possibility of an epidemic is always with us, should the unknown favoring conditions arise. In this regard it will be remembered that some three years ago six cases were reported on board the old receiving-ship Vermont, in July, 1901, and that it has been noted that in proportion to the population, according to Dr. Browning, the wards touching on the East River, Newtown Creek, or Gowanus Canal, that is, on the commercial waterways of the town, have about twice as many cases of the disease as the interior wards. Brooklyn is not an exception in this. Other cities with as carefully kept statistics show the same state of affairs.

At the May meeting of the New York branch of the New York State Medical Association, the discussion of epidemic cerebrospinal meningitis brought out many valuable opinions with regard to the differential diagnosis. As the ultimate resort lumbar puncture must remain the most important diagnostic aid. If the first case or two that occurs in the district takes on the typical appearance indicated by that unfortunate name, spotted fever, and then gives signs of spinal meningitis, the diagnosis may be easy. As pointed out by Dr. Winters, however, cases may be extremely anomalous in type and may have a very insidiously deceptive appearance from that of mild tetanus to that of severe ptomain poisoning. Under such circumstances the diagnosis can be made only by autopsy, unless the *Diplococcus intracellularis* be found in the cerebrospinal fluid. In New York this micro-organism has been practically always found. There were some patients with true epidemic cerebrospinal meningitis in whom it was not found, but they were very rare.

As lumbar puncture, besides being of distinct diagnostic value, is also of great service in relieving the symptoms of coma and other manifestations due to high pressure within the spinal canal and the cerebral ventricles, there should be little hesitation in practising it. It is easy of accomplishment, it gives practically no pain, in a severe case the child is too comatose to notice it, and it represents the best possible means of affording relief. Its frequent repetition, whenever indications call for it, as when coma becomes deeper, is the only active remedial measure at present known for one of the most fatal of diseases. It has been practised many thousands of times without any bad results, and while it sometimes fails of its purpose, owing to anomalous conditions within the spinal canal, this constitutes no good reason for hesitating with regard to its employment.

Notwithstanding the high hopes raised by the favorable reports of the intraspinal injection of dilute solutions of antiseptics, especially from Portuguese observers, this method has not seemed to be of especial service in New York.

THE LONGEST EDITORIAL RECORD.

In speaking of Dr. Shrady's retirement from his editorial position with the *Medical Record*, in our last issue, we referred to his protracted relation with that periodical as "establishing for himself the longest editorial record in the country." In obedience to our invariable rule, we take this, the earliest opportunity, to correct our own error. Although Dr. Shrady's tenure of thirty-eight years was a long and honorable one, in point of duration it does not compare with that of the

elder Dr. Hays, as editor of the *American Journal of the Medical Sciences*, which continued uninterruptedly from its establishment in 1820 to his death in 1879.

Entering as he did an uncultivated field, there was trying work for Dr. Hays before the old world could be made to lend a respectful ear to medical progress in America, as recorded in the pages of his periodical, but he lived to receive universal recognition of the merit of his pioneer labors. That his editorial career fell at a later period detracts not a whit from the value of Dr. Shrady's life work, for which the MEDICAL NEWS has no sentiment but that of respect and praise.

ECHOES AND NEWS.

NEW YORK.

Poisoned by Herb Decoction.—Two Italians are in Roosevelt Hospital suffering from belladonna poisoning. When taken to the hospital one was unconscious, the other so violent that it took several men to hold him down. The cause of the trouble is said to be a decoction made by one of the men, which both he and his workman drank as a remedy for a disordered stomach, and which was believed to be made of malva leaves. Malva leaves are said to be a regular home remedy of the Italians for stomach disorders. A few minutes after the men drank the decoction both became drowsy, but this state changed suddenly to great frenzy in the one while being conveyed to the hospital. A chemical analysis of the contents of the men's stomachs showed traces of belladonna.

Civil Service Examinations.—The State Civil Service Commission announces general examinations to be held September 10, 1904, including the following positions: Apothecary in State hospitals and institutions; architectural draughtsman; assistant steam engineer, Erie county service; bridge draughtsman; clerk; junior clerk; fireman; librarian, court of appeals library, Syracuse; physicians in State hospitals and institutions of both regular and homeopathic schools; trained nurse in State hospitals and institutions; woman officer in house of refuge and reformatories for women. Applications for these examinations must be made on or before September 3. Full particulars of the examinations and application blanks may be obtained by addressing the chief examiner of the commission at Albany.

Report of Contagious Diseases.—For the week ending Aug. 13, the Board of Health report is as follows:

	Cases.	*Diseases.*
Measles	95	8
Diphtheria and croup	211	23
Scarlet fever	50	2
Smallpox	..	1
Chickenpox	9	..
Tuberculosis	328	153
Typhoid fever	86	18
Cerebrospinal meningitis	..	24
Totals	779	229

Lying-in Hospital Appointments.—The following men have been appointed to the hospital staff: Drs. C. W. O'Connor, W. H. Sneider, E. K. Tanner, J. W. Edwards, to go on duty in September; Drs. H. I. Cauth, S. W. Hamilton, A. R. Keith, to serve in October; Drs. R. M. Beach, W. S. Buckley, H. H. Armington, to serve in November; Drs. C. L. Boyd, C. W. Chapin, H. L. J. Dollard, to serve in December. Alternates, Drs. Shanley and McCollum.

PHILADELPHIA.

Philadelphia Hospital.—William F. Defrates, member of the Board of Education from the Thirty-ninth Ward, has been appointed superintendent of the Philadelphia Hospital to succeed the late Robert M. Smith.

Hospital Beds Endowed.—Requests of $10,000 to the Presbyterian Hospital and $5,000 to the Children's Hospital are contained in the will of Cornelia Thompson.

University Dental School Returns to Three-Year Course.—After maintaining for one year their four-year course in dentistry the University of Pennsylvania has been compelled to accede to the action of the National Association of Dental Faculties and reduce it to three years. The university opposed to the last this action, but was overruled. In an announcement to present and prospective students, Dean Kirk states that financial interests compel the change, but they regard the return as only temporary; the university believes that a four-years' course will ultimately be established upon a sound basis.

Medical Colleges Criticized.—The State Board of Medical Examiners announce that of the 379 candidates at the recent examination, 73 failed, a percentage of nearly 20. The usual failures are from 13 to 14 per cent. The fault is believed to lie in the curriculums of the colleges which instruct their students in the specialties to the exclusion of broad general principles. General illiteracy of the candidates is another reason for failures. Members of the board favor an investigation of teaching methods; this, however, would require legislative sanction.

First Report of the Department of Public Health and Charities.—The report of the Department of Public Health and Charities of Philadelphia from its organization in April, 1903, to the close of that year, shows very encouraging results. Director Martin thus summarizes the most important accomplishments of the year: (1) Securing the co-operation of the profession in the way of the special advisory board and the aid of representative medical societies of the city; (2) the appointment of 37 additional medical inspectors and two eminent diagnosticians, Drs. Welch and Schamberg, for the suppression of contagious diseases and the medical inspection of schools; (3) systematic courses of instruction for inspectors in the various bureaus; (4) the appointment and organization of an adequate corps of milk, meat and cattle inspectors; (5) the building of two portable steam chambers for disinfecting and cleansing infected houses; (6) appointment of a chief resident physician at the Municipal Hospital; (7) improvements at the Philadelphia Hospital, including tuberculosis pavilions and roof garden, installation of a modern record system, appointment of a salaried director of the clinical laboratory, and the naming of two eminent consulting surgeons, Drs. Brinton and White. The most pressing needs of the department at present is a hospital for the insane established on a suitable farm, remodeling of the Philadelphia Hospital on modern lines and the establishment of a plant for the manufacture of antitoxin and vaccine virus.

Report of the Bureau of Health for 1903.—The annual report of the Philadelphia Bureau of Health for 1903 shows a general death rate of 18.82 per thousand, 1.15 higher than the preceding year. Leaving out the deaths from accident, suicide and homicide, the rate would be

17.92. During the year there were 3,043 cases of diphtheria, 4,188 of scarlet fever, 1,637 of smallpox and 8,701 of typhoid fever. All of these show an increase over 1902, varying from 295 in smallpox to 3,695 in typhoid fever. Regarding the occurrence of typhoid fever three facts are apparent: (1) Outbreaks are liable to occur at any season of the year; (2) certain wards are most affected; (3) an unusual number of cases may suddenly appear in isolated localities. The conclusion is that outbreaks are due to widespread and continuous contamination of the water supply. Occasional local outbreaks are due to other causes, and for these the milk supply is principally blamed. Special efforts are being made to locate such milks. Statistics show that the Municipal Hospital, in which are confined smallpox cases, must still be considered a focus for the dissemination of that disease. Although all precautions are taken, no permanent improvement is looked for until removal of the hospital to a new site.

Disinfection of Houses.—Experiments and bacteriological investigations have shown that the most efficient method for use in routine house disinfection is the direct application by means of an atomizer of formaldehyde in solution to all the surfaces of the rooms. The solution used is 5 parts of the 40 per cent. solution of formaldehyde to 95 parts of water, approximately a 2 per cent. solution of formaldehyde gas in water. A machine devised in the laboratory throws a finely divided stream a distance of eight feet. For each 1,000 cubic feet an amount of the solution equal to a pint of the 40 per cent. formaldehyde is used. Tests show 100 per cent. of surface disinfection and more than 85 per cent. of test objects containing various bacteria. Because of the possible presence of protozoa in the houses occupied by smallpox patients, the above process was for a time supplemented by the burning of sulphur. This was finally abandoned because of the lack of means for readily determining its efficiency, and also because of its destructive effect upon certain articles of furniture when wet from the spraying.

Widal Reaction in the Diagnosis of Typhoid Fever.—During 1903 this test was made a greater number of times than in any preceding year, many specimens coming from Butler. Out of 6,341 samples, representing 5,508 patients, there was a discrepancy between the laboratory and clinical diagnosis in 6.94 per cent. Since 1897, 28,862 examinations of samples from 24,588 cases have been made. Among them there was a discrepancy of 4.9 per cent.

CHICAGO.

Incorporation of Swedish Hospital.—Articles of incorporation were issued July 20 for the Washington Park Hospital, to be built near Washington Park. The institution has a capital stock of $50,000, and has at present accommodation for thirty patients in a building at Sixtieth street and Vincennes Avenue.

Hospital Benefits by Lawn Fête.—The lawn fête given by the St. Francis Hospital Association at Evanston last week netted $1,400 to the funds of the hospital.

Week's Deaths.—Acute intestinal diseases caused 120 of the 473 deaths for the week ended August 6; consumption, 58; violence, 44; heart diseases, 34; Bright's disease, 33, and pneumonia, 27. The annual death rate per 1,000 was 12.78, which compares very favorably with 14.29, the rate for the corresponding week last year.

Typhoid Threatens Strikers and Strike-Breakers.—Typhoid fever, which threatens to become epidemic among the strikers' families in the district west of the stock yards, is feared in the ranks of strike breakers. A non-union workman at the Armour plant has been removed from his home to a hospital suffering from the disorder. A man and a woman employed as strike breakers at the Swift plant were removed to hospitals suffering from ailments supposed to be typhoid fever.

Smallpox in Dowie's Land.—The citizens of Waukegan, Wis., are still uneasy concerning the reported epidemic of smallpox at Zion City, Ill., and are awaiting the investigation by the inspector, Dr. E. F. Baker, of East St. Louis, sent there by the State Board of Health. Dr. Herman Spalding, of the Chicago Health Department, a deputy State health inspector, visited Zion City and examined the cases there. He found sixteen cases of smallpox, but pronounced them a mild form of the disease. None of the patients has been vaccinated, however, as vaccination is not permitted in Zion City. Dr. Spalding protested against this. The sixteen patients were all quarantined at an isolation hospital, a frame structure two miles from Zion City on the lake shore. The hospital is well guarded. The houses from which the cases were taken are also quarantined and under guard.

GENERAL.

Dr. Osler Going to Oxford.—King Edward has approved the appointment of Dr. William Osler, of Baltimore, as Regius Professor of Medicine at Oxford University, in succession to Sir John Burdon Sanderson.

Dr. Osler is physician in chief of the Johns Hopkins Hospital and Professor of Principles and Practice of Medicine, to which positions he was appointed in 1888. His contributions to medical science have been many and valuable, and have made him well known as a physician, pathologist and physiologist throughout the medical world. He was born in Canada and received his education at Trinity College School and Trinity College in Toronto. He studied medicine at McGill University, Montreal, and at the Toronto School of Medicine, where the degree of Doctor of Medicine was conferred on him. He further pursued his studies in Berlin, Vienna and at the University College, London. The faculty of McGill University elected him to the chair of the institutions of medicine in October, 1874. He was elected pathologist to the Montreal General Hospital in 1875, and three years later was appointed physician and lecturer on clinical medicine in the summer session.

Dr. Osler was unanimously elected by the University of Pennsylvania to the chair of clinical medicine in 1884. He remained there a year, and in 1885 was appointed Gladstonian lecturer in the Royal College of Physicians and Surgeons, London. A short while afterward he was appointed Cartwright lecturer in the College of Physicians and Surgeons, New York. He is a Fellow of the Royal College of Physicians, London. The University of Aberdeen, Scotland, and several American universities have conferred upon him the degree of LL.D.

We are glad to be assured that Dr. Osler does not intend to sever his present relations with the Johns Hopkins University until June, 1905, or after the completion of the approaching session.

Cholera in Russia.—A dispatch from St. Petersburg states that the sanitary authorities and the police are co-operating to suppress an outbreak of Asiatic cholera in that city. There have not been many deaths, and the number is not stated officially.

Study of Mosquitoes in Montana.—The sixth session of the University of Montana biological station at Big Fork, on Flathead Lake, in that State, is engaged in investigating the mosquito. The work is especially difficult owing to their disappearance from the swamps in which they had been found unbearable in other years.

By diligent search of the pools, puddles and swampy places adjacent to the laboratory a considerable quantity of material, both in the larval and adult state, has been secured, and breeding experiments are being carried on in the laboratory. Seven distinct species have thus far been found as a result of two weeks' study. *Anopheles maculipennis* is very rarely found. This is the species that is known to carry malaria. No malaria has ever been known to have occurred in the region. The absence of mosquitoes is due almost entirely, if not entirely, to the absence of rainfall this spring. The mosquito crop comes largely from small and temporary pools and puddles, where other forms of insects do not have time to mature. The mosquito has a shorter period of life in water than most insects, shorter than that of any of its enemies, and can live where few other forms of life will exist. Clearing the region of underbrush so the sun may dry up the puddles, draining the swamps and burning débris has done much to reduce the number of mosquitoes and abate the nuisance.

Fourth Pan-American Medical Congress.—The meeting of this congress, which was to have convened the latter part of December of this year at Panama, has been postponed until the first week in January. This was done at the request of many physicians who proposed to attend it, as they desired to be at home with their families during the Christmas holidays. The delegates from this side of the continent will therefore leave on Tuesday, December 27, if they go down from New York by the regular Pacific Mail Lines, or at other dates if they go by way of New Orleans or Jamaica. The congress will be held from the 4th to the 7th of January. The dates of sailing from the Pacific Coast have not yet been ascertained. The officers of the congress appointed by President Amador, of the Republic of Panama, are: Dr. Julio Icaza, Dr. Ciro Uriola, Dr. J. Calve, Dr. Carlos Cooks, Panamanians; Dr. Gorgas, chief of the Panama Canal Sanitary Commission, Drs. Carter and Ross, Americans; Dr. Manuel Corales, Cuban; Dr. M. Stern, English, and Dr. Oduber, Dutch. This bids fair to be the most successful Pan-American medical congress that has ever been held, on account of the central situation of Panama and its easy approach from both sides of North America, Mexico, Central American Republics, as well as from the countries on the north and west sides of South America. There will be but four sections at this congress—surgery, medicine, hygiene and the specialties.

Research Work in Government Laboratories.—The recently erected laboratory of the Public Health and Marine Hospital Service is doing some very good work along experimental lines. The zoological division has been investigating the hook worm, besides doing much general work. Anything in the shape of worm or animal life affecting the human body can be sent there for determination. While specimens from private physicians have thus far been examined without charge, the laboratory will take pains not to compete with men who are conducting similar work on private account. All the drugs used in the Public Health and Marine Hospital Service, which has 60,000 patients a year, are examined in the pharmacological division. This branch of the laboratory is also on the lookout for new alkoloidal principles in drugs, and is constantly studying the effects of new drugs upon animals. This is chiefly research work. Of late some of the most important experiments have been made with quinine compounds, and although the results are not quite ready for presentation, the prospect is that some important discoveries may be announced. The aim was to secure a compound which would kill the malarial parasite that quinine is so effective in attacking, but one which would be without the ordinary disagreeable effects of that drug. Experiments have gone far enough to show a quinine derivative which is a great deal more effective on these microorganisms, but not so injurious to warm-blooded animals. The tests have not yet been applied to human beings, but the poisonous qualities of the compound have been pretty well ascertained. It takes twice as much of the new quinine to kill a mouse as of ordinary quinine, while it is known to be more effective against the malarial organism. The findings along this and similar lines are published in the laboratory bulletins, which are issued from time to time.

The American Medical Society for the Study of Alcohol and Other Narcotics.—This association was organized June 8, 1904, by the union of the American Association for the Study of Inebriety and the Medical Temperance Association. Both of these societies are composed of physicians interested in the study and treatment of inebriety and the physiological nature and action of alcohol and narcotics in health and disease. The first society was organized in 1870 and has published five volumes of transactions and twenty-seven yearly volumes of the *Quarterly Journal of Inebriety*, the organ of its association. The second society began in 1891 and has issued three volumes of transactions and for seven years published a Quarterly Bulletin containing the papers read at its meetings. The special object of the union of the two societies is to create greater interest among physicians to study one of the greatest evils of modern times. Its plan of work is to encourage and promote more exact scientific studies of the nature and effects of alcohol in health and disease, particularly of its etiological, physiological and therapeutic relations. Second, to secure more accurate investigations of the diseases associated or following from the use of alcohol and narcotics. Third, to correct the present empirical treatment of these diseases by secret drugs and so-called specifics and to secure legislation, prohibiting the sale of nostrums claiming to be absolute cures containing dangerous poisons. Fourth, to encourage special legislation for the care, control and medical treatment of spirit and drug-takers. The alcoholic problem and the diseases which center and spring from it are becoming more prominent and its medical and hygienic importance have assumed such proportions that physicians everywhere are called on for advice and counsel. Public sentiment is turning to medical men for authoritative facts and conclusions to enable them to realize the causes, means of prevention and cure of this evil. This new society comes to meet this want by enlisting medical men as members and stimulating new studies and researches from a broader and more scientific point of view. As a medical and hygienic topic the alcoholic problem has an intense personal interest, not only to every physician, but to the public generally in every town and city in the country. This interest demands concentrated efforts through the medium of a society to clear away the present confusion, educate public sentiment, and make medical men the final authority in the consideration of the remedial measures for cure and prevention.

OBITUARY.

Dr. Lindhurst C. Dodge, of Rouses Point, N. Y., died suddenly at his home on the night of August 13. He was sixty-three years old.

Dr. A. W. Warden, of Union Hill, N. J., died August 13, in the Presbyterian Hospital, from blood poisoning, contracted three weeks ago while performing a surgical

operation. He was advised to have the arm amputated, but would not consent to it, being confident of recovery. Dr. Warden was prominent in local affairs of Union Hill, having served in the Board of Education and having been the organizer of the first public library in the town. He was forty-seven years old.

Dr. JOSEPH WIENER, active in many philanthropic and scientific movements, died at his residence, 1046 Fifth avenue, August 14, of heart disease, after an illness of several months. He was born in Hauska, Bohemia, April 5, 1828, and came to this city in 1849. For thirty-five years he was actively engaged in the practice of medicine here, during a large part of this time as an associate of the late Dr. William Detmold in the chair of military surgery at the College of Physicians and Surgeons. He was also one of the founders of the department of pathology of that institution prior to its incorporation as a part of Columbia University. Dr. Wiener retired from practice more than twenty years ago. Throughout his entire life Dr. Wiener was an enthusiastic lover and collector of objects of art, and was a member and patron of the Metropolitan Museum of Art and of the Museum of Natural History. He was also a member of the Geographical Society, the Academy of Sciences, the Numismatical Society, the Symphony Society, the Oratorio Society, and various other scientific and literary organizations. He was one of the founders of the Palette Art Club. In 1885 he presented the statue of Washington Irving, which now stands in Bryant Park, to the city. He was also one of the organizers and first vice president of the Union Square Bank. During the Civil War he was chairman of the Republican organization in his district.

Dr. HENRY B. MCCARROLL died suddenly last Wednesday at his parents' home in Morristown, N. J., from pneumonia. He was born October 7, 1856, and was a member of the Yale class of '78 and was graduated from the College of Physicians and Surgeons of New York City in 1881. He spent two years in hospital work and then became an instructor of medicine in the Post-Graduate Hospital.

CORRESPONDENCE

OUR PARIS LETTER.

THE WATER QUESTION—PURIFICATION AND EPANDAGE—DRINKABLE WATER AND SEWER WATER—BIOLOGICAL PROCESS—ACTION OF MICROBES—FAILURE OF EPANDAGE.

PARIS, FRANCE, August 6.

IDEAS are like certain plants, some bloom out and fructify very quickly; others, on the contrary, take centuries to pierce and arrive to maturity. Such, for example, is the water question, which has interested man ever since drinking water has been heard of, but presents a new phase and added attraction during the last ten years on account of the necessity of epuration. Naturally men have always preferred pure, fresh, limpid water. The Romans, who were masters in the art of construction, at great expense brought drinkable waters into their cities by means of superb aqueducts, the remains of which are still admirable.

The idea has prospered since then, and the first care of every town council is to bring in good water for the inhabitants. Paris has expended more than $30,000,000 to bring in the waters of the four smaller rivers, which supply about 320,000 cubic meters of water a day besides the filtering reservoirs established for the Seine water. Our ancestors gave little attention to the cleansing of their towns. The rivers, as the Tiber of old, and as the Ganges to-day, played the part of sewers, carrying along all the filth of the towns and thus becoming transformed into a permanent source of danger to public health. In the nineteenth century the grand industrial and manufacturing outburst by the multiplication of factories everywhere added a new element, causing increased silting of the rivers and contamination of their waters. This time the evil brought its own remedy. Until then man's health alone had suffered from the contamination of rivers. Now, as these received the waste and refuse of factories, certain new substances were introduced which rendered the springs and rivers unfit even for fish life. It is no longer clear and limpid water that flows among the meadows, but a black and pestilential liquid, a source of infection and epidemy.

Dr. Calmette, Director of the Pasteur Institute at Lille, taking his example from trials made in England and Germany, has introduced into France the biological purification of residuary water. By this is meant the complete destruction of putrescible organic matters characterized by clarification and their mineralization, and not simply a mechanical separation. Microbes or fire are the only agents capable of effecting this destruction.

In the epandage or refection of water the cultivated soil transforms all the filth that is poured upon its surface into gaseous elements which escape into the atmosphere. But this is only possible with deep, porous, well-drained soils. In the experimental fields at Achères, near Paris, one hectare (2.47 acres) of one meter's depth can absorb 110 cubic meters of sewage water a day. A town of 100,000 inhabitants, reckoning 100 liters of water per day for each inhabitant, would require a surface of epandage equal to 91 hectares for 3,650,000 cubic meters per annum. At this rate this system is only possible for large towns with vast sandy or calcareous fields in their neighborhood, which must at the same time be very absorbent and of little value.

The hygienic results of experiments made at Gennervilliers, Achères, and especially at Carrieres-Triel, have been far from satisfactory. It was an error to reckon on the purifying powers of cultivated soil. Plants are only able to absorb organic matters when these are in a state of soluble nitrates. Moreover, the accumulation of organic matter favors the development of mosquitoes and flies, which are the vehicles of numerous infectious diseases. For the last ten years Percy Frankland, Gilbert Fowler, Sir H. Roscoe, in England, Hiram Mills and Kennicut, in America, have drawn the attention of sanitary engineers to this question. The system of biological epuration is employed with success in twenty-two towns in England. Manchester purifies in this way 180,000 cubic meters of sewer water a day. Formerly this town employed the system of chemical precipitation, which produced an enormous quantity of mud, which had to be carried to the sea in boats. This method of epuration, modified by Dr. Calmette, who has found the perfect solution of the difficulty consists of three distinct operations; a decanting and separation of the non-putrescible solid residues; a dissolution of organic matters in a septic covered tank under the influence of anaerobic microbes; and, lastly, a transformation of the organic matter into nitrates by their oxidation on bacterial beds, or species of epandages formed of scoriæ of metallic dross; this oxidation being performed by anaerobic microbes.

The sewer water, after a sojourn of twenty-four hours in the septic tank, and after a passage over two bacterial beds, in each of which it remains two hours, comes out perfectly pure and limpid. These bacterial beds, formed of a layer of scoriæ one meter thick, can serve three times in twenty-four hours. Each period of eight

hours is thus divided; one hour for filling, two hours full, one hour for emptying. Four hours are necessary for airing the bed.

By the study of the different methods of epuration now employed we can see, from the experiments of Dr. Calmette, successfully carried out at the village La Madeleine, near Lille, that biological epuration alone gives good results. By this process 5,000 cubic meters of residuary water per hectare can be purified in a day; that is to say, a volume of polluted water at least forty-five times greater than by epandage or refection, which only purifies 110 cubic meters per hectare.

Other experiments have been made at Say's sugar refinery of Pont d'Ardres, under the supervision of Mr. Cronier. These diverse results prove the failure of epandage, as actually practised, and foreshadow the substitution of the biological system. The cleansing of manufacturing districts and towns will thus make large strides, and hygiene will have registered another victory.

SOCIETY PROCEEDINGS.

NEW YORK STATE MEDICAL ASSOCIATION—NEW YORK COUNTY BRANCH.

Regular Monthly Meeting held May 16, 1904.

The President, Alexander Lambert, M.D., in the Chair.

Appendiceal Enteroliths.—Dr. Frederick Holme Wiggin presented the specimens of an appendix recently removed in which there were a number of concretions. The symptoms of the case had been those of a mild appendicitis. There was no perforation found, but in the neighborhood of the largest stone, there was a dangerous thinness of the wall of the appendix, and pressure had produced an area of inflammation through which rupture with consequent peritonitis would also inevitably have taken place in a short time. It is evident, of course, that these stones have taken a long time, very probably many years to form, and yet there had never been any previous symptoms of appendicitis, and nothing pointing to the existence of a serious pathological condition in the right iliac fossa.

In discussing the specimens Dr. Alexander Lambert said that the occurrence of enteroliths in the appendix were by no means uncommon, and that undoubtedly their presence frequently was the basis of the tendency to appendicitis, whenever a condition of lowered resistive vitality asserts itself, or some especially infectious material finds a lodgement in the neighborhood.

SYMPOSIUM ON CEREBROSPINAL MENINGITIS.

The principal part of the scientific business of the evening consisted of a series of papers on epidemic cerebrospinal meningitis, with special reference to the epidemic at present under special observation in many cities of this country, and the early differential diagnosis of this disease and its treatment.

Lumbar Puncture.—Dr. Thomas Wood Hastings said that since the introduction of spinal puncture much that is definite has been learned of the bacteriopathology of various forms of spinal meningitis. This puncture is usually performed by inserting a needle between the third and fourth lumbar vertebræ, the fourth being usually the best for this purpose, because the dura is adherent to the bodies of the vertebræ in this region and is not pushed before the needle. The method employed is either that of Quincke with the patient in the lateral position, or that of Führinger with the patient in the sitting position. Those who have had most experience with lumbar puncture apparently prefer the sitting position, but it is still an open question and a matter of habit rather than choice.

Therapeutics of Lumbar Puncture.—Lumbar puncture has, however, besides its diagnostic value, a definite therapeutic value. It may bring about a reduction of the pressure of the cerebrospinal fluid and thus relieve many of the patient's symptoms, especially those relating to comatose conditions. Usually, where there is high pressure in the spinal canal in adults, at least 50 or 60 c.c. are removed, though as high as 100 c.c. may sometimes be allowed to flow out to advantage. For diagnostic purposes in acute cases five c.c. of cerebrospinal fluid are sufficient. In recent years an improvement on simple lumbar puncture has been the subsequent injection of a certain amount of normal salt solution, with the idea of diluting the toxins present and perhaps even tempting some of those already in spinal cells into solution in the cerebrospinal fluid where they will be less actively harmful. Attempts have even been made to introduce other drugs, lysol and certain milder antiseptics.

Differential Diagnosis.—Whenever the cerebrospinal fluid is cloudy infection is surely present unless the cloudiness is due to hemorrhage; even when the cerebrospinal fluid is clear, if there are fibrinous threads in it, or, if after it has stood for a time, there is a tendency to coagulate into fibrous flakes, an infectious process is at work within the spinal canal. In the examination of cerebrospinal fluid for a diagnostic purpose, it is in this fibrinous material that bacteria and pathological cells are to be looked for. In tuberculous meningitis there is practically always an excess of mononuclear leucocytes. At the beginning of epidemic cerebrospinal meningitis there is always a polynucleosis, that is, a decided increase in the number of polynuclear leucocytes. Later on mononucleosis may develop.

Variety of Micro-organisms.—Nearly all forms of micro-organisms have been found in the cerebrospinal fluid. Even when the affection is of one type there may be a mixed infection of other bacteria besides those specific for the disease. At times there is a spinal meningitis, without any micro-organism, sometimes spoken of as a simple serous meningitis, because no bacteria can be found and there is a very slight tendency to fibrin formation. These cases are sometimes otogenic, that is, due to some infection from pathological process not very virulent in character near the ear. Diplococci are very common in affections of the spinal meninges. Some of them look not unlike gonococci. Gonococci, however, are rather rare. The *Micrococcus catarrhalis* occurs not infrequently. The *Diplococcus intracellularis* of Weichselbaum is thought to be the cause of epidemic cerebrospinal meningitis, and is being seen rather frequently at the present time in cerebrospinal fluid. The differential characteristics between this last organism and the *Micrococcus catarrhalis* are that the micrococcus grows on all media, and on solid media presents a rather tough growth and is quite a long-lived micro-organism. The *Diplococcus intracellularis*, on the other hand, does not grow except under rather favorable circumstances; for instance, the temperature must always be above 20° C. Its growth is of jelly-like consistency on hard media and it is a rather short-lived micro-organism.

Peculiar Disease.—Dr. Joseph E. Winters said that it is hard to speak of the cerebrospinal meningitis epidemic under any one type of disease, since it presents so many anomalies in its course. It may bring the life of a robust, sturdy child to an end in two short hours. It may leave life hovering in impenetrable incertitude

for weeks without hope and without the doctor being able to say anything definite as to the prognosis. Then, suddenly, there may be a beginning of recovery and unconsciousness may depart and complete convalescence ensue, in the midst of which, however, relapse may take place and in a few hours a fatal termination disappoint all hopes. A disease that runs as anomalous a course as thus described can scarcely be brought under a few symptomatic headings. General remarks then are likely to be more suggestive and valuable than formal classifications of symptoms and course. The disease often beggars description and one almost feels as if one were the subject of a bad dream, rather than engaged in the sober consideration of disease.

Illustrative Cases.—A patient seen recently, a child about five years of age, fell on a Saturday evening and hurt its forehead. It awoke early in the morning and asked for a drink. The father noticed that it swallowed peculiarly. A physician was summoned, but the history that the child had suffered from laryngismus stridulus some ten or twelve months before, seemed to account for this symptom. The child did not get better and after two days developed trismus. The diagnosis made then was tetanus. The port of entry for the microorganism was considered to be the injury. The temperature stayed at about 102.5° F. When Dr. Winters was called to see the case the physician was considering the idea of administering tetanus antitoxin, but Dr. Winters hesitated because of the marked involvement of the sensorium. Further study of the case showed that this was the most prominent symptom and that with the exception of the trismus there was no tendency to spasm. The disease was pronounced to be cerebrospinal meningitis, because of the epidemic now raging, and when the little patient died next day the autopsy served to show the correctness of the diagnosis. Before the death, the temperature had risen to 107° F. The length of the disease from the first symptom to the fatal termination was only five days.

Traumatic Infection.—In another patient there was a history of attempts to remove a foreign body from the ear which led to its being pushed through the tympanum. An aurist was consulted who made an incision behind the ear in order to pull the ear forward and by so doing succeeded in removing a pea from behind the remnants of the drum membrane. Eight days later, while eating strawberries and cream, the patient was taken with vomiting and abdominal pain. The temperature rose to 106° F. When Dr. Winters saw the case the most marked symptom was severe tremulousness of both hands, though there was no tremor in the legs. An examination of the spine showed no tenderness in the lower part, but distinct tenderness in the lower dorsal region and extreme tenderness higher up. It is important in these cases to learn to appreciate the reaction of the patient to pain by beginning the examination at a point where no tenderness is expected. When the child was lifted into a sitting posture there was a marked attack of vertigo, which is always a prominent sign, and the disease was set down as cerebrospinal meningitis. In another case, a large healthy girl ate a good breakfast; shortly afterward she was taken with headache and vomiting and in six hours and fifteen minutes from the first symptom was dead.

Pseudo-Appendicitis.—One little patient recently fell ill while on a visit to its grandmother and, of course, the symptoms were attributed to some overindulgence in food, because of grandmother's lax care in the matter. The little one complained of pain first in the left side of the abdomen, but later this pain seemed to become localized in the right side and the affection was considered to be appendicitis. When Dr. Winters was called in consultation there was an ice-bag over the left iliac region and the patient was better. The improvement continued for some time. Then uncontrollable vomiting set in, which was finally brought under the influence of morphine. For several days no food could be taken of any kind, and peptonized milk was given by the rectum. All tenderness left the abdomen after a time and it became very clear that the seat of the symptoms was the nervous system. In the light of knowledge of the present epidemic the affection was finally diagnosed as cerebrospinal meningitis and other confirmatory symptoms were found.

Suspected Poisoning.—In the case of four girls who fell ill at a school along the Hudson, their illness was ascribed to poisoning. The symptoms were very severe and began with vomiting and headache in all of the cases. The only thing that all of them had taken was some Rochelle salts. These were sent to Philadelphia for analysis. Two of the patients died. When called in consultation Dr. Winters was inclined to agree in the diagnosis of poisoning until he noted that the pupil of one of the patients suddenly dilated and then as suddenly contracted. This aroused his suspicion of cerebrospinal meningitis and at the autopsies, for all four of the little patients died, this diagnosis was confirmed.

Symptomatic Course.—As a rule the symptoms of cerebrospinal meningitis epidemica develop very suddenly and not with the slow gradual progress of tuberculous meningitis. The pulse is likely to be exceedingly rapid, while that of tuberculous meningitis is slow and irregular. There is a tremor present in practically every case. Usually there is some stiffness of the neck and also of the muscles of the trunk, but even when this is not present any sudden change of position is sure to be painful, unless the patient is in coma, and to lift the patient's head up always causes extreme vertigo, even in cases that are not severe. Changes of position are followed at once by great increase in the pulse and by tremor. The patient is usually afraid of being moved and skin tenderness to a marked degree is one of the most common features of the disease.

Prognosis.—When the affection has a sudden violent onset the outlook is very unfavorable. Great depression expressed by an extremely sunken countenance also has a bad prognosis. A high temperature or a very rapid pulse early in the case is likely to show a fatal termination. Mottling of the skin is another bad sign and complete involvement of the sensorium is also unfavorable. It must not be forgotten, however, that profound coma may exist for weeks and yet the patient recover completely. Nothing can be said in the meantime, for the patient may never rouse out of the coma, and yet the least favorable symptom may be the beginning of a reasonably rapid convalescence. Sudden contraction and dilatation of the pupils in these cases is likely to portend a fatal termination.

Treatment.—The abstraction of blood by means of leeches applied to the nape of the neck along the spine and to the temples is always followed by relief of symptoms. An ice-cap should always be employed as well as spinal ice-bags; this should not be considered merely expectant treatment, but, besides giving relief to the patient, it shortens the course of the disease, seems to lessen the inflammation and is thus directly curative. One of the most important drugs in this disease is opium. It should be given freely and the patient should be made, as far as possible, free from pain. This point cannot be insisted on too much. The pain itself will help to make the affection fatal, if allowed to persist. After opium the most important drug is the fluid

extract of ergot, which should be given in rather large doses from the beginning to the end of the disease. The most interesting thing about the disease, in Dr. Winter's opinion, is the uniformity of the lesions found at autopsy, and yet the multiplicity of symptoms with the very variously differing onset and course which the affection follows.

Dr. Lee, in opening the discussion, said that the medicolegal aspect of these cases is interesting, since the question of their following injury to the head or to other parts of the body may bring up the question as to responsibility for the fatal termination of the illness that follows what would ordinarily be a rather mild traumatism.

Symptomatic Course.—Dr. Morris Manges said that it must be borne in mind that adults are quite as likely to suffer from cerebrospinal meningitis as children, and that, as a matter of fact, in the present epidemic in New York, a large number of adults have had the disease in severe form and many have died from it. In his experience with these patients at the Mt. Sinai Hospital certain characteristic symptoms have always been noted. Herpes has occurred in every case. Usually it was at the angle of the mouth, but sometimes below the chin, and occurred either early or late in the disease. In severe forms roseola or petechiæ were often seen, and a form of rash that is very interesting and which was described by certain Portuguese observers who have studied a number of cases of the disease recently, is seen with great uniformity about the knees, the trochanters and the elbows. It may be described as a goose-skin appearance, but with the projecting papillæ reddened and irritated-looking, almost as if they had been stripped of their epidermal covering. A deep vermilion color is quite characteristic of some of the lesions of the disease. In mild cases this form of eruption may be helpful in the differentiation of cerebrospinal meningitis.

Eye Symptoms.—Variability of the pupils is an exceedingly valuable sign. A difference in the size is often noted first, and then sudden changes from extreme dilatation to extreme contraction, the pupils not acting synchronously, are often noticed. A deeply congested eye was one of the most uniform external features of the disease at Mt. Sinai Hospital. Strabismus is seldom lacking at some time or other in the disease, and when the patients are conscious double vision may be complained of early. Ecchymoses are seen at times and especially whenever there is a tendency to petechial eruptions elsewhere.

Headache.—One of the very common symptoms is headache, which may mark the beginning of the disease, and is sure to be seriously complained of whenever the patient does not lapse into coma. There is a marked tendency for patients who are not comatose to curl up and flex themselves as much as possible. This gives a series of patients a characteristic look by which the affection is hinted at at once. They are very sensitive to motion and are likely to resent any change of posture.

Differential Diagnosis of Coma.—Where patients go into coma without much warning, as is sometimes the case, it is not always easy to be sure that the affection is not uremic coma. These severe cases are often hemorrhagic, and if hemorrhages occur in the kidneys this may give rise to the thought of hemorrhagic nephritis from the appearance of the urine and so add to the difficulty of the diagnosis. Where sugar occurs in the urine in sudden cases the likeness to diabetic coma becomes very marked. The pressure upon the floor of the fourth ventricle by the rise in pressure of the cerebrospinal fluid may cause, at least temporarily, glycosuria. So during an epidemic this fact must be borne in mind. The differentiation must be made by the pupillary signs and by certain nervous symptoms such as Kernig's and the Babinski phenomena.

Corroboration of Symptoms.—Nervous symptoms are more apt to be present in adults than in children, and lumbar puncture with its high leucocyte exhibit is of great service. The presence of a high leucocytosis in the circulating blood is also important. In a word, the main advance in differential diagnosis has taken place by corroboration of symptoms rather than by the finding of any pathognomonic symptom or set of symptoms. The sudden onset of the disease and its rapidly fatal termination sometimes makes diagnosis impossible. A woman brought into the hospital in coma, the only previous history being the occurrence of vomiting and the gradual sinking into a comatose condition, died within two hours of admission. On the other hand, mild forms of the disease may occur, and during the present epidemic the occurrence of depression with fever from no known cause accompanied by injection of the eyes and absence of the patellar reflexes, must give rise to suspicion.

Lumbar Puncture in Diagnosis.—Where there is grave doubt as to the nature of the disease, lumbar puncture is extremely important. Ten drops of cerebrospinal fluid will give the opportunity for finding the *Meningococcus intracellularis,* and this at once settles the diagnosis. Very few cases have been observed in the present epidemic, in which the meningococcus could not be readily demonstrated. Lumbar puncture is, however, is also curative as well as of diagnostic aid. It is not done often enough. The sudden deaths that are reported in many cases of epidemic cerebrospinal meningitis would not occur with nearly such frequency if timely lumbar puncture were done and the procedure repeated as often as symptoms of coma asserted themselves. It must not be forgotten that the cerebrospinal fluid is apt to accumulate very rapidly. The introduction of certain drugs into the spinal cord sometimes seems to prevent this. One of the most promising of these is lysol. It has been used in Portugal with good results, and seems to have given some satisfaction in the present epidemic. Hot baths are very good in the treatment of cerebrospinal meningitis, and should be given as directed by Aufrecht, at a temperature of about 104° F., with massage, somewhat as in typhoid fever. Patients should not, however, be given cold baths. The skin surface is entirely too sensitive. Baths should not be given either at the beginning of the affection, when the patient is irritable and has a great disinclination to be moved about. As for drug treatment, the most satisfactory remedy is undoubtedly opium, which has an excellent effect and should always be used to save the patients the otherwise intolerable pain of which they complain.

Characteristic Symptoms.—Dr. Leszynsky said that certain symptoms should give rise to suspicion of the possible existence of cerebrospinal meningitis, now that the epidemic is on. Changes in the pupils are the most important, and after these the loss of the knee-jerks. The fever is apt to run very high, and 103° F. is rather low in severe cases of cerebrospinal meningitis. Dr. Leszynsky has employed lysol injections in one case into the spinal canal, removing ten c.c. of fluid and injecting the same amount of one per cent. solution of lysol. The patient suffered from collapse several hours later, but all the symptoms subsided and improvement set in, until convalescence was established. This treatment should not be used in milder cases.

Dr. Palmer Dudley said that lumbar puncture is by no means an easy procedure in the child, though it may be performed without difficulty in older people. It must not be forgotten that in aged people it is quite the rule not to be able to obtain any cerebrospinal fluid on ordinary puncture. There is very little danger from the procedure, however, as Dr. Dudley has employed it in a number of cases for spinal anesthesia.

Spread of the Disease.—Dr. James J. Walsh said that the most interesting problem at the present moment is how cerebrospinal meningitis is spread. We are undoubtedly in the midst of an epidemic of the disease, and any hints in this matter may prove very valuable. In Europe it has often been noticed that sporadic cases of cerebrospinal meningitis occur in tramps or in connection with people who have been living in great uncleanliness, and have moved from one part of the country or city to another. After the disease has thus been introduced into a town, it is not unusual to have several other cases occur in the neighborhood. It would be interesting to know if that special product of our modern civilization, the tramp, had anything to do with the spread of the epidemic in America. It would seem as though uncleanliness cannot be considered to have as much to do with the origin of the disease, as has been thought, since a number of the cases in the present epidemic have occurred among classes of people who are very careful of cleanliness.

Prognosis after Severe Complications.—Dr. Walsh said that too unfavorable a prognosis in severe cases is not always justified. In one case, where coma lasted for several weeks and where, after the disease, the patient was not able to walk well for several years and had a distinct difficulty in speech, all the symptoms disappeared during the course of ten years and practically a complete recovery took place. Only one sign of the disease was left, a slight weakness of the anterior tibial muscles.

Dr. Francis Huber said that cerebrospinal meningitis is an extremely variable disease and hard to diagnose. Lumbar puncture should be performed in doubtful cases, and even in small children from eight to ten c.c. of cerebrospinal fluid should be removed. Less than this had no favorable influence. In one severe case under his observation lumbar puncture was performed fifteen or sixteen times, though before its performance the patient was sometimes so violent as to need restraint. He was now improving. The operation is easy in children.

Dr. Delphey considers that the cerebrospinal meningitis is more atypical in adults even than in children. There may be convulsion, followed by delirium without retraction of the head, without stiffness of the neck and without herpes, with a temperature very little above 100° F. and pulse below 100. In such a case the diagnosis is impossible without lumbar puncture.

Septicemic Cerebrospinal Meningitis.—Dr. Maas said that during the existence of the epidemic it is possible that some cases of cerebrospinal meningitis, due to septicemia, may so closely simulate the epidemic disease as to be mistaken for it. In one case he has seen streptococci recovered from the cerebrospinal fluid and other organs in the body, showing the presence of an acute septicemia after injury.

Dr. Lambert said that in practically all cases at Bellevue the *Meningococcus intracellularis* had been found in the cerebrospinal fluid, and this is the pathognomonic sign. After lysol injections some patients get well and some do not. No treatment seems to be effective.

Dr. Winters, in closing the discussion, said that rashes do not occur commonly in certain epidemics and very seldom in the present epidemic. Lumbar puncture, Dr. Winters considers suitable only for hospital practice, and he says that the diagnosis should be made by careful observation of the patient, even though it should take several hours of noting every symptom, as tenderness, the pupils, the reflexes, the skin, and other available data.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, held May 9, 1904.

The President, T. E. Satterthwaite, M.D., in the Chair.

Discussion on the Treatment of Scarlet Fever.—This was the order of the evening, and the discussion was opened by Dr. S. Henry Dessau. Scarlet fever, he said, was a disease so variable in type at different times and in different countries that up to the present time not only was the prognosis of individual cases difficult, but it was also very difficult to estimate the value of any method of treatment, unless the number of cases treated was very large. Although the disease has always been recognized as highly contagious, until recently the most general method of treatment in vogue has been empirical and expectant. The use of tincture of ferric chloride and potassium chlorate, however, foreshadowed antiseptic treatment. With a view to the lowering of high temperature and the mitigation of the disastrous effects upon the nervous system not infrequently noted in severe cases, Currie introduced hydriatic treatment, and later this was warmly praised by Trousseau. For promoting comfort and giving tone and vigor to the nerve centers, cold affusion will probably always be employed, especially in malignant cases. The cold wet-pack does not have so pronounced an effect, but may serve a useful purpose in certain cases. Hydriatics, inunction of the body, and nasopharyngeal irrigation may be said to be the most valuable adjuncts to treatment up to the present time, while the importance of sanitary measures has also become generally recognized. It would seem that we are now on the eve of a new departure in dealing with this disease. The tendency of modern ideas is to follow in the line of bacteriological research, but it is unfortunate that the specific microorganism of scarlet fever is not yet definitely known. There is good reason to infer, however, that in association with the active element of contagion, a streptococcus, by a concurrent, or as it has been called, *symbiotic,* action, is an important factor in the etiology of complications and sequelæ which are the main causes of mortality. While it has been noted that streptococcus infection renders diphtheria more severe, the evil effects of this symbiosis appear to be ever more marked in scarlet fever. The two methods that are most worthy of consideration at the present time are the serum treatment introduced by Moser of Vienna in 1885, and the antiseptic treatment introduced by Arthur Wigglesworth of Liverpool, England.

Serum Treatment.—The original antistreptococcic serum used in the disease was that of Marmoreck; the one now used, called *new serum,* is that made after the method of Aronson and Moser. It has been largely employed by Baginsky and Moser abroad and to a limited extent by Charlton, of Montreal, Chittick, of Detroit, and Louis Fischer, of New York. In December, 1902, Charlton reported fifteen cases, all severe, with two deaths. In one of the fatal cases the child was in a dying condition on admission and lived but four hours; in the other the child had pneumonia on admission, and five days later, laryngeal diphtheria. In the others the results were marked and of such rapid occurrence that he thought they could be attributed

only to the serum, without the use of which he believed that all would have died. Chittick, November, 1902, reported six cases, and his results were much less favorable, one-half of them proving fatal. Fischer, March, 1903, reported two cases successfully treated in which there were glandular swellings, necrotic exudate, and high temperature. All these observers noted a hastening of desquamation as one of the results. In concluding this portion of the subject, Dr. Dessau gave the conclusions of Mackie as published in the *Lancet* of Feb. 20, 1904, and recently quoted in the *Therapeutic Gazette*. The first and last of these were as follows: (1) Antistreptococcic serum is of distinct value in a certain number of cases, and particularly when the throat lesion is severe and toxaemia is going on; (2) even in those cases in which it does no good there is no evidence to show that it does harm.

Antiseptic Treatment.—Wigglesworth's idea is to administer carbolic acid, in doses of from 1 to 6 grains (according to age), freely diluted, every two hours at the earliest stage of the disease, until the urine becomes smoky, and to continue the acid in diminishing doses until complete convalescence occurs. He began using this treatment over twenty years ago, and in a paper in the *Lancet* of Oct. 23, 1897, claimed that he had had no deaths and only three cases of albuminuria, all transient in character; while there was only one case of glandular suppuration. All other sequelæ were absent. The most interesting feature of his paper is his advocacy and practice of giving carbolic acid (in smaller doses), not only to the scarlet fever patient, but also to the well members of the family, and then allowing the freest communication between the attendants in the sick room and the other inmates of the household. This method, he claims, acts largely as a prophylactic, and in instances where the disease is contracted, it is invariably in a mild form. Wigglesworth contends that in accordance with the investngations of Flugge, and reasoning from analogy, carbolic acid has the antiseptic power of modifying the growth and development of the specific microorganism of the disease, so as to cause an attenuation of its virulence. In concluding his argument he says: "I think, therefore, that I am fully justified in my belief that carbolic acid given in scarlet fever does produce a virus capable of exciting a more benign malady, and, without having absolutely witnessed with the physical eye the attenuation of the scarlet fever bacterium by carbolic acid, I contend that the results I have obtained do by an analogical reasoning justify my assumption that such is produced, and that the bacterium so attenuated is in fact a 'vaccine' endowed with all the beneficial results that accrue from such attenuated cultivations. In full confidence of these results ensuing, I assert that isolation in scarlet fever is both unnecessary and inexpedient." He prefers carbolic acid as the antiseptic remedy because, unlike mineral antiseptics, it has no reaction effects, and, when freely diluted, is positively harmless. Gillespie, of Edinburgh, Dr. Dessau added, has shown that carbolic acid is Nature's own antiseptic in the animal economy, being elaborated in the process of physiological digestion. On account of his own large and favorable personal experience with carbolic acid, he said he was glad to have the opportunity of calling this treatment of scarlet fever anew to the attention of the profession, as the only reference to it which he had found since the original publication was in Bussey's article on scarlet fever in Keating's Encyclopedia of Diseases of Children. It certainly gave one the impression of a simple, safe, rational and ready method of treatment. As to the use of antistreptococcic serum, these two methods, he thought, might well supplement each other, for in one we antagonize the action of the toxin-producing complications, while in the other we inhibit the growth of the specific germs and attenuate their virulence. The same may be said of nasopharyngeal irrigation and hydriatics. Altogether, from the recorded evidence we have at hand, we are encouraged with the hope that we have at last within our means much improved methods of treating such a dreaded and fatal disease as scarlet fever.

Statistics Apt to be Worthless.—Dr. Ransford E. Van Gieson said that on account of the infinite variety of the disease statistics were of little value unless the precise conditions present were stated. It had been his fortune to pass through several epidemics of mild character; also a few of malignant type, where all treatment was futile. Here the disease was accompanied by high temperature and grave cerebral symptoms—delirium at the outset and convulsions and coma at the close. From 1800 to 1804 Graves found in Dublin a great preponderance of malignant cases, many of them terminating within forty-eight hours. From 1804 to 1837 the recurring epidemics were of a mild type.

The Use of Creosotal.—In mild cases of the disease no special remedy is required. Usually when we have put the patient to bed, regulated the diet, and ordered an occasional laxative, we have done all that is called for. In severer cases, however, this is not sufficient. Wigglesworth's record is certainly a remarkable one, extending as it does over twenty years. It is a somewhat extraordinary fact that while we have found germs for a great many diseases, the exanthemata up to the present time have baffled all research in this respect. It is still too early, therefore, to speak with any certainty as to the character of the *cantagium virum* of scarlet fever. Consequently he had taken up the old idea of zymosis as a working hypothesis, for want of a better one. He had concluded this disease to be due to a degenerated enzyme, or pernicious zymogen, as the vehicle of contagion, and had always used some remedy having antizymotic power. He began early to employ sulphite of soda. He was ever ready to accept any kind of antifermentative treatment, as closely related to the bacterial aspects of the matter, and later he was accustomed to give carbolic acid in five or six drop doses. Among the ignorant particularly, however, he found it difficult to get people to use this remedy, as it was known to be a popular means of suicide. Accordingly he took up creosotal as a substitute for it, and he had obtained just as good results with this agent. It was analogous to carbolic acid in its action and, so far as he had been able to judge, produced the same effect. The urine did not become so smoky under its use as with carbolic acid, and it could be given in much larger doses. One of the most pronounced results produced by it was a rapid fall in temperature. As a diluent for the creosotal he gave liquor ammoniæ acetatis, and he believed that this had a tendency to prevent renal complications. He had had no experience with antistreptococcic serum, but, judging from the success of the use of allotropic silver in erysipelas, he thought it might prove of value.

The Treatment of Desquamation.—He could not agree with Wigglesworth on some points. He should hesitate to say that a diminished virulence could be produced by carbolic acid or similar agents. He believed, moreover, in the strictest isolation, and the disinfection of the patient himself, externally as well as internally. One of the most potent agencies for disseminating scarlet fever was the fine particles of desquamating skin. The best means to prevent this was thorough and constant inunction of the body. Personally he was accustomed to employ for this purpose a mixture

of ten tablespoonfuls of sulphur and twice as much lard, to which were added an ounce of sodium bicarbonate and half a fluid ounce of oil of eucalyptus. He could truthfully say that he had never known an instance in which the disease was contracted from a patient, properly isolated, in whose case such inunction was faithfully carried out.

Anginose Symptoms.—The throat symptoms naturally presented different varieties, and in malignant cases necrosis commenced almost immediately. In every case, however mild, he began local treatment with the following formula:

℞ Borax..... ℥i.
Sodium bicarbonate..... ℥ii.
Potassium chlorate..... gr. xv.
Potassium permanganate..... gr. vi.

Half a tablespoonful of this to half a cupful of water was employed as a gargle or wash for the nose and throat.

The Use of Diphtheria Antitoxin.—Dr. Thomas Darlington said that in his experience it seemed to make very little difference what treatment was employed. He had formerly made trial of Déclat's carbolic acid treatment, but had not been impressed with its value. At the present time he was accustomed to begin the treatment of all his hospital cases with large doses of diphtheria antitoxin, with a view to preventing diphtheritic complications, and he had never seen any harm from this practice. Scarlet fever patients, about the fourth or fifth day, are apt to have some diarrhea, and for this he formerly gave creosote, in liquid peptonoids or other pleasant vehicle. He had found, however, that much the best plan was to give a little calomel at the beginning of the attack, as by this means such digestive trouble could usually be avoided. The great majority of deaths occur late in the disease, and the greatest danger from sequelæ is in the light cases, because, the children having the disease so mildly, the parents do not take proper care of them. As to the use of antistreptococcic serum, he had had no experience. Dr. William N. Park was at the present time engaged in an investigation of this treatment at the Willard Parker Hospital, and it was to be hoped that some reliable data might be obtained from his researches. In conclusion, Dr. Darlington stated that the Health Department had just had prepared for the St. Louis Exposition a series of charts showing the death-rate in New York from the prominent contagious diseases during the last twenty years. In these it was interesting to note that the death-rate fell very much as soon as isolation was insisted upon.

General Symptomatic Treatment.—Dr. Walter Lester Carr said that in epidemics in which the disease was of a grave type treatment was of little benefit. He had not found carbolic acid a specific, although in small doses it was useful in relieving vomiting and also diarrhea. It was also an excellent remedy when throat complications were present, and creosotal probably acted in much the same way. Inunction was undoubtedly a very valuable measure, as Dr. Van Gieson had stated. Siebert was accustomed to use ichthyol for this purpose. Personally he never hesitated to employ sponging while maintaining inunction. The varying character of different epidemics had been clearly brought out in the discussion, and, with our present knowledge, general care and the prompt treatment of symptoms as they arose, seemed to offer the best chances of success.

No Specific as Yet.—Dr. Thomas S. Southworth said there was probably no specific for scarlet fever. He thought there was no other disease in which there was so much meddlesome interference and so much in the way of proper treatment that was omitted, as in this. What was omitted might no doubt often prevent the occurrence of fatal complications. Our main object, indeed, was the avoidance of complications. There was great need of good nursing, and the proper care of the child could scarcely be carried out by the mother alone. Thus, the maintenance of nasal irrigation almost necessarily required the services of a competent nurse. There were three things which especially demanded attention: (1) The kidneys, (2) the ears, and (3) suppuration of the cervical glands.

Attention to the Kidneys.—An abundant supply of fluid was required to thoroughly wash out the kidneys. At the Minturn Hospital it was the practice to give a considerable amount of milk and of water alternately every two hours, and a large flow of urine was thus induced. Under this plan the number of cases of nephritis was very small. Kidney trouble was undoubtedly much less of a bugbear at present than in the old days when water was to a great extent denied the patient. Frequent saline enemata were also of great service from their diuretic action. He agreed with Dr. Van Gieson as to the practical value of remedies like liquor ammoniæ acetatis, which had a diaphoretic as well as a diuretic effect.

The Nose and Throat.—In every case of scarlet fever he thought a culture should be taken from the throat, in order to ascertain whether any Klebs-Loeffler bacilli were present. In all institutions it was a good practice to administer diphtheria antitoxin at the inception of the case, as Dr. Darlington had advocated, because in all these places the diphtheria germ was endemic. There was not the slightest danger from this procedure, particularly if the kidneys were kept flushed. Nasal irrigations were most important, in that they were irrigations of the nasopharynx. It was his routine practice to employ saline irrigations every four hours in all his cases of scarlet fever. The fluid, if some of it should be swallowed, was perfectly harmless. This measure, he believed, prevented an immense amount of toxic infection. Thus, it limited the extension of trouble through the eustachian tube to the middle ear.

The Use of Antistreptococcic Serum Unphilosophical.—Dr. Henry W. Berg said there had for some time been a universal desire to secure a serum that would successfully combat scarlet fever. The first available antistreptococcic serum was that of Marmoreck. It was tried here in twenty or thirty cases and then given up, as the results from it were extremely disappointing. As to the death-rate, Dr. Berg attached very little importance to this. Some years later came the Aronson antistreptococcic serum, which was far more powerful. In Aronson's own cases the death-rate was about 8 per cent., a figure by no means as favorable as is generally met with in this country under ordinary methods. Then came the Moser serum, which was more powerful still. In all these we have been dealing with a serum having an action not against the germ of the disease, but against the germ which causes the complications of the disease. What should we naturally expect from a serum which counteracts the germ of the disease itself? Undoubtedly, that under its use there should be some reduction of temperature within twenty-four or at most forty-eight hours. If such a fall occurred, we would be willing to accept it as a specific. Now, as an actual fact it is observed that under the use of antistreptococcic serum there is a decline of temperature about the sixth day of the disease. When it is considered that in the ordinary history of scarlet fever, without any treatment, the febrile movement terminates by lysis on the fifth or sixth day, it will readily be seen that this serum has absolutely no claim to be considered as a specific. It is a delusion, therefore, to suppose that antistreptococcic serum is useful in scarlet fever.

Negative Results from Antistreptococcic Serum at the Willard Parker Hospital.—The Secretary, Dr. P. Brynberg Porter, said it had been hoped to have Dr. Park present on this occasion to give some report of his recent investigations at the Willard Parker Hospital; but, unfortunately, he was away from the city. Dr. Park had, however, informed him verbally that the results from antistreptococcic serum in a dozen cases of scarlet fever had proved entirely negative. The most he could say was, that while it had not been of benefit, it had apparently done no harm.

Carbolic Acid.—Dr. Dessau closed the discussion. In regard to the difficulty of getting people to use carbolic acid on account of the prejudice against the remedy as a poison, as mentioned by Dr. Van Gieson, he said that in a large dispensary practice, in which he constantly prescribed it, he had had no trouble on this score. It was his custom to inform mothers, not that the medicine was carbolic acid, but that it had some carbolic acid in it, and that in the diluted way in which the acid was given it was absolutely harmless. The only idiosyncrasy against the remedy which he had noted was that in a few individuals it caused vomiting. This difficulty, however, could usually be overcome if its administration were persisted in for a time. Dr. Darlington had spoken somewhat disparagingly of Déclat's treatment of scarlet fever. But this treatment, in which phenol was given by hypodermatic injection, was an entirely different matter from the Wigglesworth carbolic acid treatment. It was true that we did sometimes use carbolic acid subcutaneously in the treatment of phlegmons, such as boils and carbuncles, but the dose was never a large one—not more than 10 drops of a 10 per cent. solution. Wigglesworth, on the other hand, gave as much carbolic acid by the mouth as his patients could take.

Diphtheria Antitoxin in Scarlet Fever.—In regard to Dr. Darlington's routine practice of administering diphtheria antitoxin at the beginning of all cases of scarlet fever, it was interesting to note that in Chittick's two most successful cases the patients had given them, some time after getting the antistreptococcic serum, 2,500 units of diphtheria antitoxin, although no Klebs-Loeffler bacilli were found. On the other hand, two cases in which the antitoxin was given first, and later free doses of antistreptococcic serum, did badly; one of them dying, and the other recovering only after a month's illness.

HARVARD MEDICAL SOCIETY OF NEW YORK.

Regular Monthly Meeting, held Saturday, April 23, 1904.

The Vice-President, Eugene Fuller, M.D., in the Chair.

Modern Therapeutics.—This was the title of the paper of the evening and was read by Dr. Reynold Webb Wilcox. He said that many important advances in modern therapeutics have been made with regard to physical and mechanical methods of treating disease. These are no longer used empirically, as had been the case for so long, when their employment was rather in the hands of the quack and the charlatan, than of the regular practitioner, but are now employed on definite scientific principles. Some of the changes in the rationale of their use are extremely interesting and represent distinct landmarks in the progress of therapeutics. The cold bath, for instance, is no longer used with the idea that it reduces fever, or as a general nervous stimulant, but it is rather employed for the purpose of eliminating various toxins through the kidneys.

Climate and Mineral Springs.—Dr. Wilcox said that there has come a complete realization that there cannot be an ideal climate, since the first necessity would be equability of temperature, and this cannot exist without a dampness that is eminently unsatisfactory. The climate must not be too dry, however, for it has been learned that large and rapid daily changes of temperature must of necessity follow. With regard to mineral springs and the effect of mineral waters, modern medicine is in a much better position to know the chemical composition of these waters and what can be looked for from them and what not. Besides the chemistry of mineral waters, there has come a great advance in our knowledge of the physical chemistry of such solutions and the study of various radio-activities as are associated with mineral waters is opening up another and probably a brilliant chapter in internal hydrotherapeutics.

Electricity.—This is no longer looked upon as a cure-all, but definite indications for its employment are well recognized. The very high tension electricity, as developed by Dr. Morton in this country, and the use of high frequency currents, have made electrotherapeutics a much more important chapter and with a much more rational basis than before. The effect of electricity upon the blood vessels and the consequent stimulating effect of variations in blood pressure are now well known and show the lines in which this department is going to develop. Static electricity is no longer used merely empirically, but has a definite set of indications and can be made in proper conditions and with appropriate direction to give definite results.

Pure Drug Therapeutics.—Drug therapeutics has lagged somewhat behind physical and mechanical therapeutics as regards its establishment upon a firm rational basis. There is no doubt now that the new physical chemistry, the most brilliant chapter in chemical development at the end of the nineteenth century, will soon remedy most of this defect. Already this has been accomplished for familiar drugs and the end is not yet. At the beginning of the nineteenth century the use of all drugs was based upon empiricism. As the result of German nihilism, unfortunately there was for a time, in scientific hands, a neglect of drugs that kept therapeutics in the background, while pathology and other departments of medical science were advancing with giant strides. Even at the present time many so-called text-books of medicine are scarcely more than treatises on pure pathology. With regard to treatment very little is said. So much is this division of the book overshadowed by the rest that often it occupies brief paragraphs where the others have pages devoted to them. This is, of course, as it should be, since a text-book of medicine must be helpful not alone in the recognition of disease, but especially for its cure, as far as that is possible and for its care if cure cannot be obtained.

Physical Chemistry of Drug Treatment.—If drug treatment is to be successful in modern days and if its true rationale is to be recognized, then the basis of the explanation of drug effects must be along the lines of physical chemistry. It must not be forgotten that at various times varying explanations for the action of a drug may be offered and accepted, and yet the truth as to its real therapeutic effect not be known until the real cause of the disease has been recognized. Until Laveran discovered the cause of malaria, it was impossible ever for therapeutists to give the true reason for the action of quinine in the disease. Much had been said about its supposed effect on fever, of its effect on the white blood cells, it was when it had been found that it acted unfavorably upon the *Plasmodium malariæ* that the real explanation became evident. The empir-

ical fact of the usefulness of quinine was unsatiable. The explanations offered for its effect, however, were many and had to be changed with the progress of science until at last truth came.

Basis of Drug Therapy.—Drug therapy is now being put on a much more secure basis, by observations in the laboratory. This does not change the views with regard to the employment of remedies, but often helps to make it clear how they may be used with better effect. Digitalis is now used on a very different theory from that on which it was originally introduced, but the indications for its employment are the same as when Withering first wrote with regard to it in 1784. The most hopeful thing with regard to present-day drug therapeutics lies in the development of physical chemistry. It is but a few years since Faraday introduced the word ion and the idea which it conveys. Only now is the pregnant idea of his coming to bear fruit in a new science of chemistry. In the days when Lister recommended carbolic acid as the most important thing for securing asepsis, generally the material was employed in varied solution. However, by experiment and observation it came to be known that in oily solution carbolic acid did not inhibit bacterial growth. It was not until the application of Faraday's theory to chemical compounds brought out the fact that electrolytes are not set free when in oily solution that the real explanation for this failure of carbolic acid, under these circumstances, could be understood. The same explanation has been found to be helpful with regard to solutions of mercury, and even with regard to many biological phenomena where it might be least expected to have its application. The formation of rouleaux in the blood, that is, the clinging together in series of the red blood corpuscles, is really a phenomenon of ionization. The Widal reaction receives its best explanation on the ionic theory. The action of toxin and antitoxin on one another are phenomena of ionization. These phenomena can now be measured with exactness by the Wheatstone bridge, as was demonstrated at our last meeting, and Kohlrausch has determined the conductivity of fluids with reference to their contained electrical units. There are practical applications of these theories, as for instance the pleuritic fluids and their possible absorption and to the urinary contents that look very promising.

Pharmacopœia.—While the profession in America had an excellent pharmacopœia for use, one that is generally considered more valuable than that of any other nation, not even excepting the German, very few physicians have been sufficiently familiar with it. One hundred and fifty professors of therapeutics were asked why they thought the pharmacopœia was not more used in this country. Over thirty of them answered that they considered the main reason for the neglect of the pharmacopœia by the medical profession was its unwieldy size. It is evident that even these professors of therapeutics made the mistake of taking the United States Dispensary for the pharmacopœia. If such is the case, Dr. Wilcox ventures to say that a very large proportion of the practising physicians of this country do not know the pharmacopœia because they have been deterred by the supposition of its size, while it is really only a comparatively small book, yet contains, well arranged, some of the most indispensable information a physician can have who is intent on prescribing rationally without the supposed aid thrust upon him by overzealous manufacturing chemists.

Pharmacopœial Development.—The United States Pharmacopœia was first formally issued in 1817, when it was decided that some legal standard was required for drugs and drug preparations. Until 1840 it continued to be published in Latin and English, but since then has been published only in English. Physicians would find that it contained nearly everything they needed to prescribe, and many helpful suggestions. Every ten years, as the result of invitations to medical schools and various medical and pharmaceutical societies, a committee of revision was selected, consisting of twenty-five members, who see to the elimination of drugs that are no longer used and to the introduction of remedial materials of various kinds, than have been introduced to medicine during the preceding decade. The book thus made is the legal standard, and is adopted by the Custom House, the Army and the Navy, as well as most of the States, as the place of last appeal for formal and legal information with regard to drugs. The next edition, which is to be issued within a few weeks, will contain besides the other information the dosage of the various drugs and remedies that are incorporated in the pharmacopœia.

Students and Drug Therapeutics.—At a recent discussion of the American Therapeutic Society the question was asked why medical students do not know more about therapeutics, since, as a rule, most of them are anxious to learn what to do for disease and yet are graduated, without practical training in the use of remedial agents. In the course of the discussion it was brought out that there is too much teaching of the theory of treatment and too little demonstration of the practical work of drugs either on animals or on patients. Medical students must have definite courses in the action of drugs, as these can be exhibited on animals, and then may be introduced to the classification of drugs with the idea of widening their knowledge as well as of suggesting the grouping of materials related to those whose action they have seen. Then the medical profession in this country will escape the opprobrium of Dr. Holmes's satire, that they sometimes use drugs of which they know nothing for diseases of which they know less. His other expression, used more in jest than in earnest, perhaps, that 'twould have been better for men, though worse for fishes, if all the drugs jest than in earnest, perhaps, that 'twould have been bettion.

Simplicity of Therapy.—Dr. Charles G. Schram said, in discussing the paper, that the keynote of therapeutics must be simplicity in the use of remedies. The day of complicated methods of cure is over. One remedy is used for its definite effect rather than a gunshot prescription with the idea that something in it will touch the right spot and help the patient regardless of the effect of the rest of the drugs in the mixture. The striking expression of the distinguished professor of cutaneous diseases at Harvard who said, "use vaseline if you do not know the ointment that you want to use exactly, but do not prescribe an ointment on general principles. Use lime water, if you do not know what you consider to be the proper lotion that you should employ, instead of prescribing something of whose effect you are not sure. The human organism is very delicately balanced and drugs misapplied easily do damage. The first rule must always be *non nocere*, not to do any harm. The next must be to treat the individual, and not the affection with which he is suffering.

Teaching of Therapeutics.—Dr. A. B. Duel said, in continuing the discussion, that the teaching of therapeutics a few years ago, even in good medical colleges, was apt to be rather farcical. The professor did a good deal of reading of facts and dry lecturing with regard to drug actions until the student finally got hold of a compend, boned the matter up and passed his examination. With regard to clinical application of drugs, so little was said that the student carried away next to nothing. The professor of clinical medicine spent nine-tenths of his time in the discussion of diag-

nosis and etiology and of pathology, and said only a few brief hurried words with regard to treatment at the end. Some men who got hospital work were given a training at the hands of distinguished clinical observers, but found that their use of drugs was entirely empiric and had very little reference to the scientific drug actions, as stated by the specialist in therapeutics. At the present time a change has come over that sort of teaching. But the medical student of to-day is eminently to be pitied. He is in the midst of three fires. There is the laboratory man who wants most of his time; the professor of clinical medicine, who wants him at the bedside for many hours a day; finally, there is the specialist who considers that the only hope for practical medicine is in the devotion of more time to the specialties.

Diagnosis Versus Therapy.—Dr. Edward Foote said that the science of diagnosis was definite and sure, yet difficult and required the most careful teaching from the very beginning, if its practice were to become the routine necessary for the successful practice of rational medicine. Rightly, then, the medical schools insisted so much more on diagnosis than on treatment. Treatment is much more uncertain, varies to a certain extent from year to year, can be learned from books, as diagnosis cannot, and consequently can be neglected with more impunity, or, at least, have less time devoted to it with smaller danger to ultimate success of the practitioner of medicine.

Formularies.—Dr. Henry Spooner said that medical students are told much about drug actions, but are apt to know little or nothing about the look of drugs or the combinations of them. Hence the tendency to secure formularies and make selection of prescription. In those whose tendency is not in this line, the ready-made formulas of the manufacturing drug houses make an easy and facile resort which cannot, however, but prove serious for the practice of medicine.

Dr. Whitman said that as a graduate in medicine he had scarcely the faintest notion of practical therapeutics, and one of his earliest hospital reminiscences impressed upon him as a memorial of drug action, was the effect of various cathartic remedies. The hope of drug therapeutics, however, seemed to his mind to consist in the gradual evolution of the mechanics of drug therapy, so that their use will be established on a firm rationale.

Dr. Fuller said that students should be taught the simple effects of a few drugs, and these of course the important ones. The attempt to crowd into their brains all therapeutic knowledge inevitably swamped them with undigested information, and they had to begin for themselves by learning the action of a few drugs. Dr. Fuller believes that drug houses should be made responsible for what they put upon the market, and for the alluring advertisements, often without any basis in truth, by which they attempt to bring about the introduction of their remedies. Professors of therapeutics should impress the young practitioner, about to begin his career, with the fact that most of these much-advertised remedies are without any proper efficaciousness. Personally, Dr. Fuller has never used any of the new remedies until they have been at least five years before the public. Then time and the experience of the many, has usually sifted out those that are helpful and eliminated the useless preparations. It is interesting, however, to realize that Doctors are ever avid for ready-made prescriptions. At the Post-Graduate the announcement of a prescription is always followed by the appearance of note-books and the waking up of students in order to take it down. They are all evidently interested in getting at the details of practical medicine, but they cannot trust to their memory for the indications for drugs, making combinations for themselves, but prefer definite formulas. This is evidently a manifestation of the same spirit that leads them to take up with the various ready-made prescriptions offered by the drug houses.

Dr. Follen Cabot said that at least physicians who have graduated should know what substances are incompatible in prescriptions. This should be true not only for the chemical incompatibilities, which, if they are serious, the druggist will usually correct or at least ask about, but especially with regard to the therapeutic incompatibilities. How often does it not happen that in a prescription in which a number of ingredients occur some of the materials have directly opposite physiological action to that of others or at least tend to modify and neutralize such action. This, of course, nullifies the value of the prescription.

Number of Drugs.—Dr. Wilcox, in closing the discussion, said that there is much more in the practice of therapeutics than the mere administration of drugs, though this seems to fill so large a space in the minds of many medical practitioners as almost to exclude other and extremely important therapeutic measures. Old customs in medicine seem to counsel not only many drugs, but very frequent administration. He remembers distinctly in hospital treatment seeing one medicine given before and another after meals, regularly three times a day, with a sleeping draught at night and a laxative potion in the morning. Altogether the patient looked to eight different times at which health-giving medicine was to be administered. Undoubtedly this had a good suggestive effect, whenever it was not undone by the action of the medicine. At the present time, however, the tendency is very fortunately toward simplicity of remedies and much less frequency of administration.

Therapeutic Successes.—Those who are discouraged with regard to therapeutics should remember some of the facts and statistics of present-day treatment. Formerly 75 per cent of patients attacked by laryngeal diphtheria died. Now between serum and intubation 75 per cent. recover. The former death rate from typhoid fever in hospital treatment was eighteen per cent. Now the mortality is not more than two per cent. As the result of the use of quinine 95 per cent. of the cases of amebic dysentery recover, though formerly this was a very fatal and persistent disease. For rheumatism Sydenham said the only treatment was six weeks and flannel. About a century ago Cullen said the only thing for rheumatism was six weeks and patience. Now with proper use of the salicylates the disease usually does not last more than six days. Without minimizing diagnosis, pathology, or etiology, it is easy to understand that treatment is more important than any of them. Diagnosis is much easier than intelligent therapy. There are certain improvements in the teaching of therapeutics, however, that should be introduced and with the present spread of laboratories and the tendency to include demonstrations in all courses in medical schools actual contact with drugs, remedial agencies and experience with their effects on animals is much more common than might be thought by those who graduated twenty years ago.

Validol in Seasickness.—K. Koepke (*Therap. Monatshft,* June, 1904) believes he has discovered a specific against seasickness in validol. The patient receives ten to fifteen drops on sugar and is instructed to lie down; in almost every case the vertigo and nausea disappear and small amounts of food can be retained. If the theory that seasickness is caused by cerebral anemia is correct, validol probably acts by raising the intracranial blood-pressure.

BRITISH MEDICAL ASSOCIATION.[1]

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

(Continued from Page 327.)

Army and Navy Service.—The president of this section, Surgeon-General Bradshaw, made a few appropriate introductory remarks commenting on the great importance of the hints that meetings of this kind give to the profession and also of the striking benefit to the soldier and sailor as a result of these conferences.

Camp Sanitation.—Major C. E. Freeman said that the sanitation of camps is a subject of vital importance to all, whether representing the navy, army, or volunteers. Camps in war time fall into two divisions: temporary and standing camps. The tendency nowadays is to replace temporary camps—that is, those occupied for twenty-four to forty-eight hours only—by bivouacs, doing away with tents altogether when on the march. As far as experience goes, at any rate in South Africa, the results of this procedure were good. The men seemed to get quickly hardened to the open-air life, while the relief to the transport was, of course, enormous. With the increased celerity of movement demanded by modern tactics on the march, the bivouac will in future always replace the camp. All that can be done in these hasty encampments and bivouacs is to apply the due principles of camp sanitation as far as time and means at disposal will permit. Owing to the shortness of the halt there is no great likelihood of infection arising, and if steps be taken to keep the source of the water supply clean, to prevent the actual ground occupied by the troops from being fouled, to dig a latrine trench and rubbish pit in a suitable position, and to cover in the trench and set fire to the rubbish on departing next day—that is as much as he can accomplish. If other troops following after occupy the same ground, danger arises, and great stress should be laid on the importance of using fresh sites wherever possible to encamp on. The principles of camp sanitation find their chief application in the standing camps, which are a necessary and important feature of every campaign. It is here that sickness and epidemic disease usually break out—seldom among troops who are on the march. Looking broadly at the problem these camps are congested areas, often with populations of 20,000 to 30,000 inhabitants, and having a minimum density of population in the infantry regiments of 226 men to an acre, which is greater than that of the most crowded part of Whitechapel (Notter and Firth). This crowded community has a ready-made water supply, drainage system, abattoirs, or scavenging arrangements. The inhabitants are crowded in their tents to an extent never met with in civil life, and have but small facilities for personal cleanliness. They are often worn out by fatigue and privations, or wearied by home sickness and the deadly monotony of military routine. It is to be wondered that when infectious disease breaks out in these circumstances it tends to spread like wildfire. Owing to the complexity of the problem the precautions called for must be somewhat elaborate, and it will be best to touch lightly on each point in succession, speaking in more detail on the questions which are the chief subject of this paper.

Tents.—There is nothing to be said in favor of the bell tent, and a ridge-pole tent is now being introduced which seems better in every way. A similar form of tent has been adopted in India. It is needless here to expatiate on the evils of overcrowding in the tents, and on the advantage of disposing the camp as widely as possible. Animals in camp should be picketed as far from the tents as circumstances will permit, as they of necessity foul the ground and attract flies. The usual arrangement with cavalry, artillery, etc., of having the horse lines in the center of the camp may be necessary for military exigencies, but it is bad sanitation.

Water Supply.—This is a burning question. The important point is to secure if possible a decent source of supply, and to take every care to keep it uncontaminated. This is far better than taking water at haphazard—very possibly with a dead camel or horse lying by—and trusting to boiling or filtration afterwards; for the more the water is handled the more likely it is to be infected, and the dirtier it becomes, while great care and supervision are required in its storage. Therefore a resort to boiling or filtration unless certain that the water was impure is not advisable. To this rule, however, one exception should be made. Cholera is so greatly a waterbone disease, that if an outbreak of it were dreaded, as a precaution all the drinking water should be boiled or filtered. Of these two modes one would recommend boiling, as the Pasteur or Berkefeld filters are rather delicate mechanisms to handle in the field. Boiled water as weak tea would soon become a fairly popular beverage.

In a standing camp a system of elevated cisterns can often be improvised, thus doing away with the frequent movements of water carts, and ensuring the maximum protection to the water.

Food.—The question of rations does not concern us here, but the field kitchens do, and much care is required to keep them clean and so to prevent a plague of flies. The great point is to teach the cooks to put all the fragments of food, etc., into empty tins, and not to throw everything on the ground and trust to sweeping it up afterward. If this is allowed, the ground quickly becomes foul and a center of attraction for flies. All organic rubbish must of course be burnt in the kitchen fires. There is a curious tendency in camps, which we have to fight against, to put the kitchens and latrines close together. The medical officer must see that they are kept as far from each other as possible, otherwise flies of course pass from one to the other and the food is infected.

Latrines.—These are the crux of camp sanitation, especially when viewed in the light of recent discoveries as to the rôle played by flies in the spread of disease. In standing camps latrines are of two patterns, either the trench or the pail system. The latter is much to be preferred, as trenches rapidly get filled up and fresh ones have to be dug, thus continually extending the danger area; while under the pail system the excreta are removed away from the camp altogether. This pail system can, of course, only be carried out in favorable circumstances and in camps of a fairly permanent nature. The buckets must be in good order and sufficient in number. The soil carts must be efficient and perfectly watertight, and the pits where the excreta are disposed of must be situated well away from the camp, and the water supply must be dug not too deep or too large, and be regularly filled in daily. An adequate staff of scavengers must be provided, and careful and regular supervision of all these details by a medical officer will be required. Unless all these requirements can be complied with the pail system is better not attempted, as the buckets will be foul, sewage will be dropped about the camp and the night-soil pits will become a filthy morass. If fresh chloride of lime is available, some may be thrown into the trench with the dry earth.

1 From advance sheets of the *British Medical Journal*, by courtesy of the editor.

It has bactericidal properties and its odor discourages flies. Lime is useless, as are all disinfectant powders. Pioneers must be detailed to take charge of the latrines, otherwise the trenches and their surroundings speedily become foul in the last degree. Screens must be improvised, not only for decency but also to prevent wind and dust storms blowing the dried excreta, etc., about the camp—a common and obvious source of infection in India and South Africa.

Sanitation in Volunteer Camps and the Disposal of Refuse and Excreta.—Surgeon-Lieutenant-Colonel P. B. Giles said that a powerful factor against efficient sanitation in volunteer camps is that the general system of laying out the camp is left to the quartermaster and adjutant and to the entire exclusion of the medical officer, and so frequently the best sanitation is not secured. It is quite true that volunteer camps are only intended to be used for a short period by the various units camping; but as it so frequently happens favorite localities are used year after year more or less all the summer, and so get foul, and because the purpose of camping is to give practical instruction, it has always seemed to me that as the dangers of camp life to a great extent are the diseases that are preventable, the proper course would be to start with all the precautions that should be observed if the conditions were actual service against a foe.

First, he considers that any attempts to restrict and curtail the area of a camp are risky; cramping the area of a camp may not under other favorable conditions at once show anything unhealthy, but experience goes to amply prove that in all localities in which camps are formed, and continued, that certain diseases will sooner or later occur, generally in the inverse ratio of the period over which the ground is occupied, and therefore all attempts to curtail the area of a camp and so concentrate humanity will result in sickness. Secondly, that the illnesses peculiar to camp are *de facto* such as are common to those who live in crowded and ill-ventilated localities—namely, diarrhea, sore throat, rheumatism, conjunctivitis, pneumonia, dysentery, simple continued fever, enteric. Thirdly, that the best way to prevent these diseases of camp is to obtain the best ventilation, cleanliness, disposal of refuse, disposal of excreta.

Bell tents he considers very unsanitary. The new double tent has its drawbacks, in that it lessens the germicidal activities of the sun's rays. He is not in favor of the water bottle. It is difficult to keep clean. Is more frequently used for beer. Becomes infected readily, and is not conducive to that all-important feature of military life—thirst control. Earth pail latrines he thinks better than trenches. All refuse should be burned.

Naval Dietary.—Staff Surgeon J. Falconer Hall said that the new scale of dietary came into force October 1, 1903, and since then one has had time to form an opinion regarding it. In discussing the question of naval dietary one has always to remember that compensation (or savings, as it is called) is allowed for certain articles of food that are not taken up, and much of this money is spent in the ship's canteen on various other foodstuffs. A short review of the different articles of diet is here given:

Soft Bread.—This is supplied at all the home ports, as well as most of the ports abroad, and is of a very good quality, though now and then, especially abroad, an increase in the amount of crust would be an improvement; two-thirds of the bread must be taken up.

Biscuit.—This ration is issued when the ship is at sea. It is a very popular ration, and from its composition it will be seen that its nutritious value is very high.

Fresh Meat.—The meat supplied to the service is of very good quality, being especially so at home ports. Where fresh mutton can be procured at a reasonable price, it may be issued as a change, if the men desire it. In any case, two-thirds of this ration must be taken up.

Fresh Vegetables.—The vegetables may consist entirely of one kind, or of various kinds. At home ports, potatoes are very often supplied, with frequent changes to fresh green vegetables. Abroad, the fresh vegetables issued depend almost entirely on the part of the world where the ship may be. This ration is only issued with fresh meat. In most ships potatoes are part of the canteen stock, where they can be purchased by the men.

Spirit.—An ⅛ pint of rum is issued to warrant officers and men over the age of 20. This is served out immediately after dinner. Savings may be taken for this ration, or the following substitutes: (1) ¼ oz. tea, ½ oz. soluble chocolate, and 1¼ oz. sugar; (2) ¼ oz. tea and 2¾ oz. sugar, or (3) ¾ oz. soluble chocolate, and 2 oz. sugar. The Admiralty also allow ½ a pint of wine, or 1 pint of porter, as the equivalent of the ⅛ pint of rum. Porter is usually only issued in ships on the West Coast of Africa.

Jam.—The jams supplied consist of the following descriptions, namely, strawberry, black currant, apricot, plum, gooseberry, and orange marmalade. Marmalade is issued at least on two days a week; the other days of the week the men have their choice, but only one variety is issued on any one day. In the ship one is in at present very little of the jam is taken up; but one is quite sure that in a foreign station all of it would be taken up.

Condensed Milk.—This is of the unsweetened description. No savings are allowed for this article; this is a very good thing, as it can be used for tea, or to make puddings, etc.

Compressed Vegetables.—These consist of several kinds, namely, mixed vegetables, haricot beans, shredded beans, cabbage, carrots, onions, sliced potatoes, and spinach. These are to be issued as far as possible in the varieties that the men like. The following rules have been framed for the cooking of these vegetables. The vegetables are to be placed in a small meshed net and taken to the cook the night before, who will soak them properly in hot water; this is a most important point, and the water should be changed several times during the process. The next morning the vegetables will be steamed by being placed on special gratings fitted to the coppers.

Preserved Potato.—This ration has been done away with, and a very good thing, as it was never palatable, and could really only be used for thickening soups.

Tea, Cocoa and Coffee.—The new scale provides for one ration of cocoa, one of coffee, and two of tea. At present very little coffee is taken up; this will no doubt increase as the men get to know how to make it properly. At present tea is the most popular beverage; it is now issued to each mess, and the men can make it as required. Cocoa is always issued the first thing in the morning; the men are very fond of this ration.

Preserved Meat.—This ration, for dinner or supper, consists of corned beef, boiled beef, or boiled mutton. This is issued in the kinds preferred by the men as far as possible. Corned beef as a rule is the favorite.

Salt Pork.—This is a very popular ration, and all the issue is usually taken up.

Salt Beef is of a very good quality, but is not so much liked as the pork.

None of the other articles of dietary require any special notice.

(To be Continued.)

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 85. NEW YORK, SATURDAY, AUGUST 27, 1904. No. 9.

ORIGINAL ARTICLES.

DELIRIUM FROM NERVOUS SHOCK.[1]

BY PEARCE BAILEY, M.D.,

OF NEW YORK;

CHIEF OF NEUROLOGICAL CLINIC, VANDERBILT CLINIC; CONSULTING NEUROLOGIST TO THE ST. LUKE'S AND ROOSEVELT HOSPITALS, NEW YORK CITY.

UNDER the term delirium are included mental states characterized by psychomotor unrest, insomnia, clouding of consciousness, incoherence of speech, to which may or may not be added hallucinations, illusions, and unsystematized delusions. Delirium owns many causes. As a temporary complication of febriculæ, at the height of the fever, it is hardly considered a disease. Occurring later in the course of certain infections, notably typhoid fever, pneumonia, influenza, rheumatism, erysipelas and cholera, it has the characteristics of a true psychosis, and oftentimes a psychosis of very exhausting character. One of these characteristics is lack of high fever, which indicates the action of toxins rather than of bacteria. Similar in symptoms to these toxic cases are those which follow physical exhaustion generally, but especially such states of exhaustion as result from losses of large quantities of blood—notably after surgical operations and puerperal conditions.

While these psychoses are essentially of temporary character, the prognosis is not universally favorable. When they manifest themselves in brains markedly predisposed to insanity, the mental defects are often permanent; and when associated with conditions of great physical exhaustion, they not infrequently end fatally. Varying with the fancy of the classifying alienists, they have been given a variety of names, prominent among which are toxic insanity, acute exhaustion delirium, collapse delirium, confusional insanity, acute primary mental confusion, amentia, delirium grave and the like. It is probable that little more is indicated by this diverse nomenclature than the degrees of severity and the causes.

Thus amentia is mild and of favorable omen, while delirium grave, as described by Spitzka, is without exception fatal. Fundamentally, all these cases are similar in their symptoms—namely, in a delirium of varying degrees of activity, with the physical manifestations of debility, pinching of the features, dryness of the mouth and tongue, abnormalities in the heart action and gastro-intestinal disorders. Although not generally put there, traumatic delirium belongs to the above category.

Nearly all forms of insanity have head injury advanced as a cause, but the only variety that can be regarded, with any degree of certainty, as resulting from *trauma capitis* alone, is traumatic delirium. This psychosis appears immediately or succeeds by a few days the unconsciousness due to the injury. In its symptoms and course it is hardly to be distinguished from deliria of other origins. Like them it has an uncertain prognosis, varying with the degree of injury to the brain and with the individual acted upon, alcoholism being the most important predisposing cause.

Another frequently mentioned exciting cause of delirium (especially of the type most frequently described as confusional insanity) is nervous shock, under which term are included sudden fright, grief, remorse, and perhaps even joy. This factor is one to which it is always difficult to ascribe an appropriate causal value; one, also, which is often invoked as a sole cause when it is really only one of many.

The importance of emotional factors in the causation of either somatic or mental diseases cannot be minimized. No one, be he physician or layman, can doubt the active part played in the production of disease by the contributing causes of the emotions. It is seen in daily social life, in the routine practice of medicine, and especially after great catastrophes and tragedies, such as explosions, battles, conflagrations, earthquakes, tornadoes, etc. In Reibal's paper descriptive of the Siege of Strasburg (*Gaz. Méd. de Strasburg*, 1877, XXXVI, 86-91) a graphic account of such effects is given.

The bombardment of Strasburg lasted from August 15 to September 28, 1870. The terror to the inhabitants of the town was indescribable. Shells, bombs, fuses, were sent almost uninterruptedly into the heart of the city. To this were added the fires, which raged everywhere. At times the city streets were said to be practically full of molten iron and lead and burning débris. Reibal describes seven cases of cerebral disturbances, two of which will be again referred to, in which a fatal issue was the direct result of the bombardment. In at least four cases, the patients were already infirm. He also observed two cases, in women, of epileptic convulsions. Neither had had convulsions previously. In one case the convulsions disappeared—in another they became regular in occurrence. These convulsions were regarded as truly epileptic, and were differentiated from hysterical convulsions. Reibal also saw one patient in whom itching, as the initial symptom of a fatal diabetes, developed while she was huddled in a pit where she, with others, had sought refuge from the flying shells. Subsequently to the siege, also, he noted a great increase in the number of cases of diabetes; and of deaths, from cerebral causes, in infants.

[1] Read before the Clinical Society of the Elizabeth General Hospital, at Elizabeth, N. J., January 19, 1904.

But, important as emotional factors are in causation, to prove them unique factors is a different matter. Psychic shock may, doubtless, induce heart failure or apoplexy. But in such cases, vascular disease pre-exists. Sudden death with emotional factors as a cause is not mentioned in Brouardel's "Death and Sudden Death," and I feel safe in saying that the case is yet to be advanced in which life ceased as the immediate consequence of such causes alone. General medical diseases are rendered worse by emotional causes, and resistance to them is lessened thereby. But they do not originate in such causes, whatever the Christian Scientists may say to the contrary. Of the diseases of the nervous system, the neuroses are the only ones in which fright and similar causes are really important causes. Chorea commonly, and paralysis agitans and exophthalmic goiter in a few well authenticated instances, have been the unique results of fright. Squiers (*New York Medical Record*, 1887, XXXII, 190) reports the case of a girl frightened by a plate falling on her, in whom the pulse rate changed from 75-80 to 135, remaining at the latter rate for two years, up to the date of the communication. Fright figures prominently also, in the etiology of epilepsy, though it probably causes true epilepsy only in persons predisposed to the development of the epileptic habit.

Hysteria and neurasthenia are the neuroses in which emotional causes figure most prominently in etiology. In the majority of cases, associated with the fright or other similar cause, is some bodily injury, trifling though it may be. With this physical factor present, the emotional cause loses in importance more or less, varying with the personal equation of the observer. Thus, dependent upon the mental inclinations of different writers, the traumatic neuroses arise from causes chiefly material or chiefly psychic. (In litigated cases some bodily injury must be proved. Whatever the mental or moral effects of an accident may be, it is not a cause of action unless there be some bodily injury. See Mitchell vs. Rochester Ry. Co., 151 N. Y., p. 107.) Either neurasthenia or hysteria may result when the causes are purely psychic, but in a large number of such cases marked predisposition of the affected person is demonstrable.

In insanity, with its complex and little understood etiology, it is well-nigh impossible to single out any one factor as the sole cause. Emotional factors operate here more commonly and more effectively than in somatic diseases. But the opportunities of error in assigning causes are great. Many forms of insanity, such as general paresis, in which we know there is an etiology distinct from the emotions, begin, in sequence to a nervous shock, with symptoms of delirium. When insanity begins in persons with marked predisposition, any apparent exciting cause loses greatly in importance. Recurrent psychoses set in quite commonly after the most trivial and (in themselves) inadequate causes. And many other emotional disturbances in the predisposed occur in a way to make it evident that the symptoms are not the products of any exciting cause, but are merely the fluctuations of deep-seated disease, which appear either independently of exciting causes, or as the results of such disharmonies of existence as all mankind must undergo.

In studying the literature relative to this subject, I was surprised to discover how few cases there are in which insanity can legitimately be regarded as the result of nervous shock, the test being, absence of predisposition and other causes, and a nervous shock of great intensity.

It is the object of this paper to call attention to a few cases in which these conditions are fairly well fulfilled:

Case I.—This case possesses the advantage of being full in the important details bearing upon the patient before, during, and after the accident. The accident was the tunnel disaster in New York City on January 8, 1902, which was the result of a rear end collision on the tracks of the New York Central and Hudson River Railway. The patient, W., had been, prior to the accident, an active man without hereditary taint, and with no history of syphilis or alcoholism. He was fifty-four years of age, married, with healthy children. He had built up a large and lucrative business, in which he was the senior partner. He had general supervision of the business, made all the estimates for orders, and had personally conducted large exhibits at expositions, the last being the exposition at Buffalo. The following account of the accident is from his own recollection of it. It has been substantiated in all important details by statements of others. W. was in the rear car near the middle, seated alone, and was absorbed in planning the day's work when the train stopped. In about five minutes there was a terrific crash. The rear end of the car seemed to be lifted up and turned completely over. The top was broken in by the top of the tunnel. The next thing W. knew he was lying by the side of the engine that had run into the train from behind. He was pinned between the brick wall of the tunnel and the boiler of the engine in a space not more than two feet wide. He was lying by the side of the boiler with his legs pinned down and fastened in the débris. His feet were caught between the seats, which were jammed so closely together that he could not put his flat hand between them. The engineer asked if he should not back the engine, but was told that he would tear them all to pieces if he did. The steam escaped in volumes, and the heat was almost unendurable. The fear of being scalded and of fire was frightful. There were two ladies back of W., one of whom was screaming terribly, being badly lacerated, with ear hanging, and nose being driven up into the head. Her head was hanging through one of the arches of the tunnel, and she kept calling for some one to keep her from falling. W. reached back with his left hand, and with great difficulty straightened her up. He held her in this position for at least three-quarters of an

hour. There were others near him, screaming, one with the top of the car apparently resting on the top of her head. She screamed that she was dying. The steam came constantly up into her face. W. tried to lift the top of the car but could not. There were several dead bodies in the débris close by. In about an hour two men came with a crowbar, and began to pry open the seats. The ladies were taken out first, and the roof of the car cut open to let the steam out. The lower part of both of W.'s legs were crushed, and he could only lift them by taking hold of the lower part of his trousers. He was put on a stretcher and lowered to the tracks, carried up the tracks a way, and then up the steps and into a Bellevue Hospital ambulance. His suffering was almost unbearable, and lasted until he became unconscious when put in the ambulance. He did not regain consciousness until after entering the hospital. He remembers it, but it was all like a dark dream, and he does not know how much of what took place is real or the creation of his fancy. It seemed to him as if he were going into a slaughter-house.

These gruesome details are necessary to enable one to picture the terrific mental agony undergone by all who were conscious while imprisoned in the semi-darkness in which this tragedy took place.

At Bellevue Hospital W. was found to have compound fracture of both bones of both legs, without other surgical injuries. There were no scalp wounds or contusions about the head, and there is no reason to suppose that he had sustained any cranial injury. The day after admission to Bellevue Hospital he received a good many visitors, and on the afternoon of that day he went into a condition of partial stupor. After this condition had existed for a day or two, he was transferred to a private hospital in the care of Dr. John B. Walker, in consultation with whom I saw him on January 13, 1902. While in the private hospital, prior to my examination, his sleep had been much interfered with, he was out of his head most of the time, and muttering constantly, much of which was unintelligible. He was restless, but the crippled condition of his legs prevented him from getting out of bed. He would hold both hands up in front of his face, and say that he saw the headlight coming down on him all the time. There was no vomiting. To the questions I put to him at the first examination, he gave no answer, and it was only with difficulty that he could be induced to perform such simple movements as putting out the tongue, etc. He lay in bed with eyes closed most of the time. From time to time he would suddenly open them, raise himself up from the bed, hold his hands out in front of him with face averted, but would say nothing. For two days he had to be catheterized, and on one occasion had an involuntary passage of urine in the bed. The temperature never reached 100° F. There was neither suppuration nor pulmonary symptoms to explain the mental condition. The pulse varied from 80 to 108. There was no paralysis of any cranial nerve nor of the hands. Both legs were in splints so the knee-jerk could not be examined. Two days later the condition was practically the same. In response to questions the patient would sometimes make inarticulate replies, and sometimes would not answer at all. He still made the movement of putting his hands before his face. He picked at the bedclothes, and his eyes wandered about the room. On January 16 he was somewhat better. He spoke to me, put out his hand, said "How do you do," and asked what my name was. He said that people were constantly coming to see him, but he did not know who they were. Said that the attendants had tied him down so tight yesterday that he couldn't make anything out of it. Many of his remarks were incoherent, but he evidently recognized people in the room, and appreciated the fact that his mind had been clouded for some time. On January 18 his mind was somewhat clearer, although he still did not know where he was, and could not remember names. He was tested at this examination for reading and writing. He was unable to read, and could not write intelligently at dictation. I next saw him on January 22. On that day he did not know the name of the hospital where he was, said he "remembered me from having seen me between two points in the North Shore." He said that one of his legs was splitting up into three branches, and the other had a "tap" on it. He thought he was setting out flowers. On January 29 there was evidence of great physical exhaustion, shown by very low tension pulse and weak systole. The mental state remained about the same, although at night he was apt to become very much excited. He began slowly to improve, and in the course of a few days, his mind became very much clearer. On February 8, however, he developed erysipelas, and with the fever accompanying this infection the symptoms of delirium returned, and were present for ten days or more. I did not see him again until June 13, 1902. He had left the hospital, had no further symptoms of delirium, and was able to get about a little on crutches. He said at that time he was sleeping well, that he only waked up two or three times during the night, and slept until five o'clock in the morning. This amount of sleep was still below his normal standard. His appetite, he said, was good; he had no headache, but was entirely unable to endure physical or mental effort. He had great tremor of the tongue and of the hands. He was able to read understandingly, but was inclined to slur over many words. Many simple words he did not understand, and some he could not read correctly. Thus, for *colleagues* he read *collect*, for *repudiation* he read *reputation*, for *directorate* he read *directors*. In writing there was evidence of great tremulousness, and in very simple sentences he forgot to dot his i's. He left out letters, he left out words, and some letters he seemed entirely unable to make. Of simple problems given him in addition, multi-

plication, subtraction and division, the addition was correct, the multiplication was left incompleted, the subtraction was wrong, and the division he was unable to do. Asked to subtract mentally, 31 from 66, he said it was 29. In counting small change he made mistakes. Asked what day of the month it was, he said it was June 14, 1892. He then looked around to see if he was right with an air of uncertainty, and corrected himself to 1902. His memory for the time preceding the accident was perfect, and that for the time immediately after the accident good. But from shortly after admission to Bellevue Hospital memory was very defective.

My next examination, made on February 11, 1903, gave practicaly the same results as that of June, 1902. The patient complained of dreams of terrifying character, which woke him up in the night very much alarmed and frightened. Said that he had tried to resume his business, but had been obliged to give it up. He found that he was very inaccurate in his business transactions, and that being in business made him very much more nervous. He still had serious defects in that part of the mental sphere which has to do with language and numbers. He made mistakes in words and in reading, and after reading could not give the meaning of a simple sentence. In writing, also, he misused words in a way which destroyed their meaning. He said that he had not written any business letters since the accident. His speech was somewhat thick, there was tremor of the tongue, and there was also distinct interference with the intellectual mechanism of speech. He used words incorrectly, and many words he did not seem to understand. For example, he said "in revelation of" instead of "in relation to." Much that he read he did not seem to understand. When reading a few sentences about a yachting cruise, he thought it was an account of the Spanish War, and in reading about white duck suits, such as are worn in the tropics, he thought that the wearers of the suits got them to shoot ducks with. Given the same problems in arithmetic as at the previous examination he made the same mistakes.

My last examination made October 15, 1903, showed improvement in many ways, but no real change in fundamental conditions. He made the same mistakes in arithmetrical problems, in reading and writing. With the exceptions previously noted, his memory was perfectly clear, although he was uncertain about many of his facts. He had returned to business, but was unable to take any active part in it. He said that he made so many mistakes in writing, that he now never wrote a letter unless some one read it over afterward, and that the making of estimates, which formerly had been his specialty, he was now entirely unable to do. He was unable to take orders over the telephone, as he had difficulty in comprehending what was said rapidly, and could not remember the orders when the telephonic communication was over. From the earliest period of his illness his mental state became worse on any concentrated effort. When he began to clear up a bit from his original delirium, a few moments' conversation would cause him to relapse again into delirium. This condition of ease of fatigue is still present. He can do the first arithmetical problem quickly, and with better chance of being right, than he can the fourth. There have never been any hallucinations other than those incidental to the delirium, and never any fixed delusions. I feel no hesitancy in saying that exaggeration played no part in the case. There was none of the exaggeration of the ordinary neurasthenic type, as he vigorously combated and resented the idea that his mentality was affected. Neither was there any of the exaggeration so common in litigation. He took little interest in his claim for damages, which was settled without trial.

To briefly resume: A previously healthy man, after a severe mental shock, lasting about two hours, during which he is obliged to make muscular exertions and receives serious injuries of the extremities, passes into collapse delirium. This state, in addition to the ordinary mental symptoms of delirium, manifests itself by weakness of the muscles of the bladder, and by a weak heart. About to subside, it is again called into activity by a complicating infection. At its final subsidence the patient is left in good physical condition, but with the following mental defects: Slowness in perceptions, and indecision and instability of recent memory impressions; absolute uncertainty in the arithmetical faculty; decided impairment in the faculty of written and spoken speech. Such a mental state is distinct from the delusional one of hysteria. With neurasthenia it has more in common, especially in that it is aggravated in every way by fatigue. But the absolute mental defects in the case described are not found in simple neurasthenia. The neurasthenic is capable of all, though his capacity be of short duration. Our patient is in several respects incapacitated. The early and subsequent history of the case suggest a close analogy with the pathological mental states and their results occurring as the direct sequels of the infectious diseases, of surgical operations, and of conditions of exhaustion generally. With psychic shock as the chief etiological moment, we are obliged to assume an exhaustion of the cortical cells brought about by brief, but excessive, stimulation.

Case II.—Mrs. S., twenty-seven years of age; had always been normal mentally; gave no history of hereditary taint. She had been happily married for five years. One miscarriage, no children. On December 22,1897, she saw her husband, to whom she was very much attached, walking on the street with a young and comely woman. From the other side of the street she watched the pair, until she saw them disappear in a house. She waited, and soon saw a light lit in one of the upper rooms of the house, and her husband come to the window and draw down the shade. When the husband returned to his own house, less than an hour afterward, he found his wife in tears and

unwilling to be comforted by any explanations he had to offer. She said her heart was broken, that she could never trust him again. She did not sleep that night, and the next day was still more disturbed. The condition of insomnia, grief, and agitation became progressively worse until, finally, I was called in consultation, five days after the occurrence, by the family physician, Dr. A. H. Ely. The patient was in bed, in seemingly good physical condition. There was no fever. She had passed no urine for twenty-four hours. The mental picture was that of confusion. The patient did not know where she was. Did not recognize that Dr. Ely and I were physicians, but took us for some of her former acquaintances. Said at one time that she had not seen her husband (who was in the room) for six weeks; at another, for three months. She had the illusion that strange people were in the room. When asked questions would make irrelevant replies. The occurrence which was the cause of the attack seemed to have disappeared from her mind. She could not be aroused to a realization of her surroundings. This condition of affairs lasted for two or three weeks; then the patient began to improve, and made a perfect recovery. Up to the present writing she has had no relapses.

Case III.—(Binswanger, "Ueber den Schreck als Ursache psychischer Erkrankungen," *Charité Annalen*, 1879).—Binswanger reports a case of a woman, who, although always timid and easily frightened, had never shown symptoms of mental alienation. There was no insanity in her family, and she had healthy children. On learning that one of her tenants had hanged himself in her house she fainted, but soon recovered herself. She then began to cry and bewail and could not be comforted. She continued to cry and moan, day and night, for five days, and then she began to wander in speech, and to throw herself about the room. She neither slept nor ate, and paid no attention to those about her. A little later her attention could not be aroused, the sounds she uttered were no longer intelligible, she sat rigidly with head between knees, offering resistance to any interference, including attempts to feed her. Ten days after the fright the bowels and bladder were evacuated involuntarily; the patient had not slept, but was tired and restless. On the eleventh day she died in coma. The autopsy showed multiple punctate hemorrhage in the cortex, in the cerebellum and on the base of the brain. Such pathological changes as were present in the cerebral blood-vessels were distinctly atrophic in character. There was no local arterial disease. The walls of the arteries were, however, weakened throughout, and Binswanger explains the case by assuming a sudden rise in blood pressure from the fright.

Case IV. (Landgraf: *Friedreich's Blätter für gericht. Medicin*, 1885, XXXVI, 458-65).—A little girl of 7½ years; a normal child, apparently, in every way, was frightened by two boys dressed up as ghosts. She rushed home, crying "Oh! my eye! My eye!" Without giving further explanation she sank exhausted to the floor, vomited and went into severe general convulsions. These continued till the child died less than ten hours later. The municipal report (Bayreuth) stated that the autopsy showed no anatomical cause of death, other than an excessive distention of all the blood vessels of the brain and cerebral membranes.

Case V. (Manson: *Lancet*, 1846, II, 582).—A girl, 2½ years of age, previously normal, was greatly frightened on October 2 by a boy in a mask. She could give no explanation of the cause of her fright. She trembled violently, and all she could say was "The bogie, the bogie looked through the window at me." Her health declined rapidly. On October 14 she was restless, calling "Bogie, bogie." The next day she did the same, and went into convulsions which were confined to the diaphragm and face—sobbing and sighing—that evening she died. The autopsy showed great congestion of the brain and its membranes.

Case VI. (Reibal: *Gaz. Med. de Strasburg*, 1877, XXXVI, 86-91).—A physician was suddenly forced to leave his house which had been set fire to by a bomb. He soon developed terrifying hallucinations with insomnia and agitation, which gave place to coma and paralysis. He died in five days.

Case VII. (Reibal: *Op. cit.*).—A boy of ten was frightened by a cannon ball, which passed close to his head. He ran home, but was immediately taken with chills, vomiting, delirium and convulsions, and died in a few hours.

The above cited cases give a general idea of the character of the symptoms, and the variations in their severity, which result from nervous shock in presumably normal persons.

The mental symptoms are essentially delirious. In severity, they vary, from slight and transient attacks of mental confusion, to profound disturbances of consciousness with the physical symptoms entailed thereby.

In outcome, there may be complete and permanent recovery, or recovery with defect, or as shown in the very instructive case of Binswanger, the symptoms may become progressively worse and end fatally.

Into more specific statements regarding the clinical behavior of these cases it seems impossible to go. They are, in the first place, too infrequent to permit of generalization. Further, the two causal factors, the exciting moment and the individual acted upon, are so extremely variable, that a large number of collected and assorted instances would be necessary before any definite deductions could be drawn. As has been said, such a number of cases is not available.

While the pathology of delirium from nervous shock is entirely in speculative domains, there are strong reasons to suppose that it is closely connected with disturbances in the cerebral circulation. Certain it is that evidences of disturbed circulation are always present. In fright, the blood first leaves the

body surface, there is tumultuous and rapid action of the heart, and probably an increase in blood pressure. Increased blood pressure in frightened animals has been demonstrated by Conty and Charpentier and by Bezald and Dainlewsky. (See Werner, "Ueber die Geisteskrankheiten nach Kopfverletzungen," *Vtljahrschft für gerichtl. Med.*, 23, 1902.) After the initial period of excitement, the effects upon the circulation are different, doubtless, in different cases. In some there is persistent tachycardia. In others the pulse is slow. A fall in blood pressure follows the initial rise. Vascular instability is shown in the changing character of all the symptoms.

As has been said, the symptoms of delirium from nervous shock are strikingly similar to those of the insanity characteristic of head injuries. It is highly probable that traumatic delirium is due, not to the mechanical disarrangement of brain constituents, but to changes in blood supply and pressure, and in brain pressure.

It seems reasonable to suppose, therefore, that traumatic delirium and the delirium from emotional causes are closely allied in pathogenesis, as they are in their clinical aspects.

A NEW PORTABLE SPHYGMOMANOMETER; ALSO A BLOOD PRESSURE CHART.[1]

BY THEODORE C. JANEWAY, M.D.,
OF NEW YORK;
LECTURER ON MEDICAL DIAGNOSIS, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE, AND VISITING PHYSICIAN CITY HOSPITAL, NEW YORK.

It is with considerable reluctance that I added to the rather long list of instruments for determining human blood pressure, but, after using almost all the previous forms, my desire to possess one which could be easily taken about in my hand-bag, and yet be substantial and accurate, impelled me to do so.

The main defect of most of the existing sphygmomanometers, which use Riva-Rocci's method of circular compression, is too small width of compressing surface. Von Recklinghausen, in 1901, demonstrated conclusively that no armlet less than 12 cm. wide can give accurate readings in arms much above the average size. No instrument with such an armlet was obtainable when I began my experiments, but Erlanger has since modified his excellent, though scarcely portable, apparatus by the introduction of a cuff of this width, and Stanton has brought out a fairly satisfactory instrument, with a compromise armlet of 8 cm. Apart from these, no portable apparatus used rigid tubing, or a wide enough caliber of manometer tubing to allow satisfactory transmission of the pulse wave, and the estimation of diastolic pressure. Under certain circumstances, especially for diagnostic purposes, this is of distinct value.

For my purposes I solved the problem of combining portability with accuracy, by not attempting to pack all the parts of the apparatus in one case. The armlet and inflating bag are not breakable, and can be carried with the case containing the manometer in an ordinary instrument bag. It seemed unlikely to me that any one would carry a sphygmomanometer without also taking some other instruments, and therefore a small hand-bag, with him. All the parts together weigh only 2½ pounds, and the manometer case measures 10¼ inches in length.

The instrument, as shown in Fig. 1, consists of three essential parts:

(*a*) Manometer, of U-tube form, with upper part jointed, fixed to the under side of case lid. The scale is graduated empirically for each manometer, since even-calibered tubing cannot be had in this country. The caliber used is 3 mm. The jointing of the manometer tube is copied from Cook's ingenious instrument.

(*b*) Compressing armlet, consisting of a hollow rubber bag, 12 by 18 cm., with a valve-stem for connecting with manometer. This is provided with a loose thin cover, for protection, and is attached to an outer leather cuff, which fastens by two encircling straps with friction buckles. This arrangement of straps was the fruit of considerable thought and experiment, and, in my hands, has proved a satisfactory method of fitting arms of all sizes with the same cuff.

(*c*) Inflator, an eight-ounce Politzer bag with valve. This was first used for the purpose by Erlanger, though without the valve, which has become necessary with the large armlet. Heavy pressure tubing is used for the connections. The technic of the instrument follows:

To set up the Manometer.—Unhook the lid and pull it up until it stands plumb. Drop the catch on each side behind and push the hook over the pin on brace to left, thus fastening the manometer securely in an upright position. Push the brass stop-cock (E), which contains a needle-valve, through the hole in the front of the case. Attach tube and Politzer bag (C) to it. Insert the upper joint of manometer tube, giving it a twist to make sure that the joint is tight, and slip the rubber band over the top. Slide up the scale until the O point is level with the top of the mercury column in both tubes.

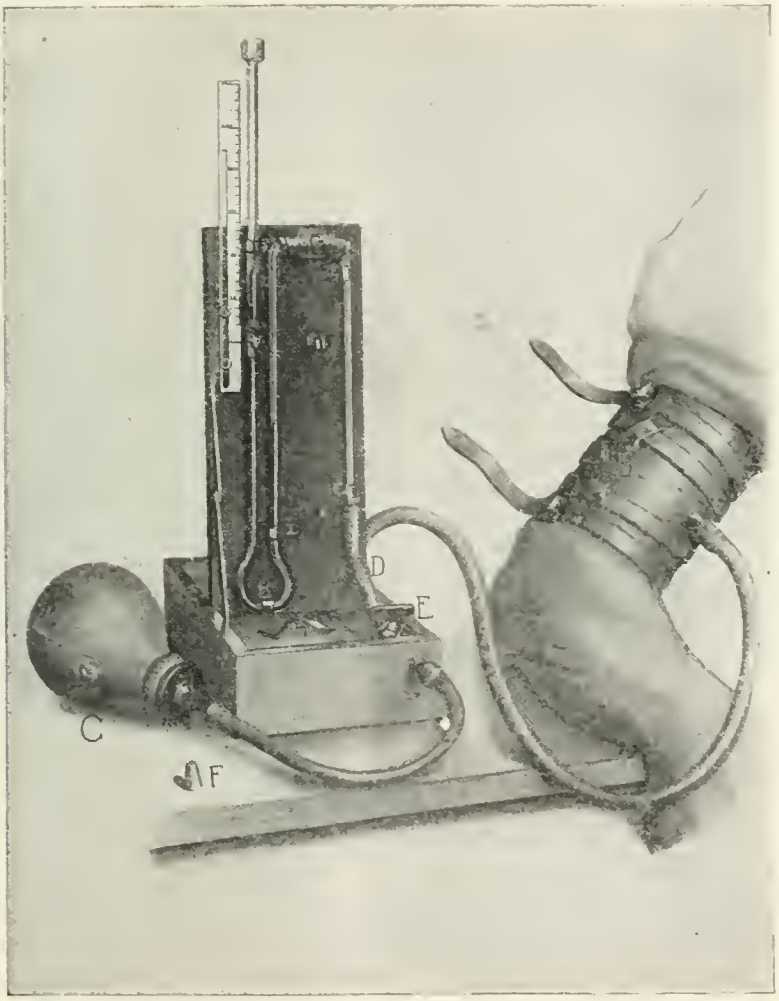
Directions for Use.—Adjust the armlet carefully above the elbow, the outlet tube over inner border of biceps. If the arm is very small, the straps will have to be passed over the slits on the end of the cuff which laps inside, not through them as usual. For children the thigh may be used. Have the cuff fit as snugly as possible without squeezing. Observations may be made with the patient either lying or sitting, but should always be in the same posture. In either case the armlet should be at the level of the heart. The patient must be at rest, as exertion, excitement and apprehension all raise the blood pressure. With one hand feel the radial pulse. With the other squeeze the Politzer inflator until the pulse disappears, then release the pressure very slowly and note the height of the manometer column at the moment the pulse is again perceived. Immediately raise the pressure just

1 Received for publication April 6, 1904.

enough to obliterate the pulse and make a second reading as it is released again. The average of these two gives the systolic arterial pressure. (Criterion of Vierordt and von Basch.)

If difficulty is experienced in controlling the pressure with the hand, close the stop-cock (E), when the pulse has been obliterated. By manipulating the stop-cock the air may be allowed to escape slowly through the needle-valve and the reading easily made. It is quicker to work with the hand alone, but requires a little practice. the pulsation of the mercury column at each point. This will increase for a time, then continue of same extent for some millimeters. At a definite point the height of pulsation will decrease rapidly. The last point at which it is greatest is the diastolic pressure (criterion of Marey and Mosso). Two measurements of this should be made. Unless a pulsation of 5 mm. is obtained, no accurate measurement is possible. This happens in rapid or very small pulses and with too loose adjustment of the cuff.

Fig. 1.



Sphygmomanometer in Operation.

When the tension is high, the air in the Politzer may be insufficient to give the required pressure. In such cases, close the stop-clock, allow bag to refill, then, while squeezing it, open the stop-cock and raise the pressure as high as desired. With high pressure, be sure the upper joint of manometer is tight.

To Estimate the Diastolic Pressure.—After obtaining the systolic, allow the pressure to fall 5 mm. at a time through the needle-valve, watching

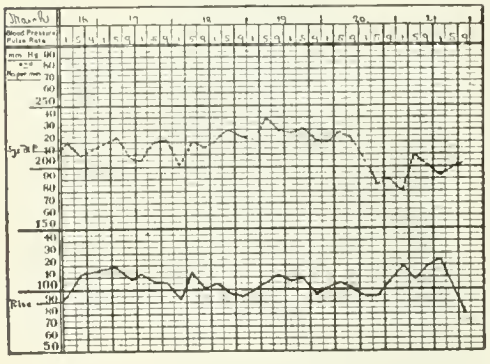
To Close the Manometer for Carrying.—Remove upper joint and place it in the rings to right. Insert cork (F) firmly in open end. Unhook the brace, drop catches at back, and shut the lid, locking it tight. The rubber joint (G) is automatically closed by a block at bottom of case. The stop-cock is to be caught under spring (H). If the mercury column breaks in carrying, shake it down before removing the cork. To fill manometer, use a medicine dropper, and, if drops do

not go down freely, run a thin wire through the tube to insure their passage into liquid below.

This sphygmomanometer is now being made for any who desire it, by Chas. E. Dressler and Bros., 143-145 East Twenty-third Street, New York City. Mr. Dressler has been of great assistance to me in solving many of the mechanical difficulties met with, which required several months' time to overcome. The needle-valve is his own construction. My own instrument has now been in use for three months and has proved quite satisfactory. In the hospital, like every instrument I have ever had there, it has suffered too much from careless usage, and I have had made a more substantial one piece manometer, without a folding case, for service in my wards. In other respects it will be found to be the same instrument.

In my hospital work I found it so difficult to obtain satisfactory blood pressure records, either on modified temperature charts, or on any of the engineer's ruled papers, that I devised the accompanying chart for the purpose (see Fig. 2). Its

Fig. 2 (reduced).



important features are: legibility at a distance; a single column of figures for blood pressure and pulse rate (also respiration if desired), so that mistakes in charting cannot occur; availability for observations at short intervals, or for b. i. d., q. 4. h., or q. 3. h. records; especially the adoption of the ordinate scale of the U-tube manometer tracing, 0.5 mm. = 1 mm., so that the curve of blood pressure obtained clinically can be compared exactly with tracings made in the physiological laboratory, and are not distorted by a purely arbitrary spacing. In use, systolic pressure is recorded by a solid red line; diastolic, broken red; pulse rate, solid blue or black; respiration, broken blue or black. At operations a double-ended pencil, red and blue, makes a chart which can be read across the room. These are made for me in blocks of fifty by George W. Buskirk, Sixth Avenue and Thirty-fourth Street, who is prepared to supply them to any gentlemen who desire to procure these accurate and convenient charts for recording their observations.

36 West Fortieth Street.

OSTEOPLASTIC AMPUTATIONS.[1] [2]

BY ALEXIS V. MOSCHCOWITZ, M.D.,
OF NEW YORK;
ADJUNCT ATTENDING SURGEON TO MOUNT SINAI HOSPITAL.

THIS article is based upon the following major amputations by osteoplastic methods, which I have had opportunity to perform on the First Surgical Division of Mount Sinai Hospital since May 18, 1900. One amputation of the thigh; one Ssabanejeef amputation at the knee; three amputations of the leg; one amputation at the ankle-joint; one Pirogoff amputation; and one amputation of the thumb. In addition I have also had occasion to perform a number of pure and simple exarticulations, and a number of amputations without any osteoplastic procedure, which are more than interesting, when studied in conjunction with osteoplastic methods. Furthermore, during this time I have always availed myself of various opportunities to carefully examine all amputation stumps which chance threw in my way, no matter whether performed by osteoplastic methods or not, so that, I believe, I am now entitled to speak with less reserve than when my first communication on this subject appeared, in the MEDICAL NEWS of February 9, 1901.

It is not essential for my present purposes to go into details in the presentation of my cases; I shall confine myself therefore to the briefest possible abstract from their histories, and to a severe criticism of the ultimate outcome in those cases in which it is indicated.

Case I.—A. T., eighteen years of age, was admitted to the hospital January 11, 1900. There was a long antecedent history of tuberculosis of the left ankle-joint, and many operations had been performed for its cure. Osteoplastic amputation in the middle of the leg performed May 18, 1900; followed by primary union, and patient was discharged June 10. The result is perfect, not the slightest pain or tenderness; patient wears an end-bearing artificial leg.

Case II.—B. D., thirty-two years of age, was admitted to the hospital June 21, 1900. Diagnosis, gangrene of anterior portion of foot due to Reynaud's disease. June 29, at the express request of the patient, a Pirogoff amputation was performed, but the gangrenous process soon involved the incision, necessitating an amputation at the seat of election on July 7. Patient was discharged August 15. The bad result in this case was due to an error of judgment, which led me to accede to the wishes of the patient for a low amputation, while only a higher one was indicated. Certainly no blame for its occurrence is to be attached to the method.

Case III.—B. A., thirty-four years of age, was admitted to the hospital August 7, 1900, with gangrene of the right foot due to Reynaud's disease. August 11 amputation of the leg by the Ssabanejeef method. The operation was easily and rapidly performed, and was not followed by any

[1] Read by invitation at a meeting of the Waterbury, Conn., Medical Society, March 14, 1904.

[2] Received for publication April 27, 1904.

shock. Four and one-half hours after operation the temperature rose to 107.5° F., and one hour later to 108.5° F.: in spite of energetic treatment patient succumbed soon thereafter. At autopsy nothing of consequence was found. August 11, 1900, was a particularly hot and muggy day, and we came to the conclusion that the fatal outcome in this case was due to insolation; this view is borne out also by the fact, that another case (radical operation for inguinal hernia), operated upon on the same day, was followed by the same train of symptoms. Certainly no blame for the fatal outcome is to be attached to the particular method of operation.

Fig 1.

Osteoplastic Amputation of Thumb.

Case IV.—W. K., twenty-five years of age, was admitted to the hospital August 14, 1900, with an infection of the interphalangeal joint of the left thumb. The joint was incised and drained, but the adjoining surfaces necrosed, necessitating an amputation, which was performed August 25 by the Bier method. On account of the extensive infection secondary sutures were used, and but very little hope was entertained for a good result. We were agreebly disappointed, however, as the bone flap united, and, after tying the secondary sutures, primary union resulted. (Fig. 1) Patient was discharged cured September 2. Some two years later I had occasion to examine the stump and found it to be absolutely devoid of pain or tenderness.

Case V.—A. S., fifty-six years of age, was admitted to the hospital October 30, 1900, with a rapidly growing sarcoma of the big toe. November 2 amputation in the upper third of the leg by the Bier method. A marginal necrosis of the bone flap occurred. On account of metastases it was deemed most wise to hasten the closure of the sinus by removing the flap on January 20, 1901. Patient was discharged March 3, 1901. At the secondary operation we have gained the impression that in due time the necrotic areas would have become exfoliated, leaving ample covering

Fig. 2.

Osteoplastic Amputation of Leg.

for the sawn surfaces of the tibia and fibula, and in no way marring the ultimate result: but on account of extensive metastases it was not deemed worth while to wait for a separation of the necrotic areas.

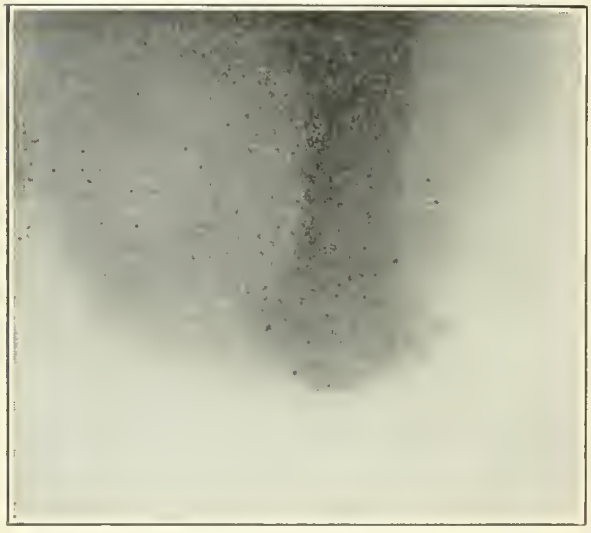
Case VI.—M. R., nineteen years of age, was admitted to the hospital June 3, 1901, with a tuberculosis of the right ankle. The joint was resected on June 7, going wide of the diseased area, but in spite of this there was a recurrence, necessitating a number of secondary operations.

Finally the case came to an amputation, which was performed October 21 by the Bier method. (Fig. 2) Primary union resulted and patient was discharged cured December 4. Several months later I had occasion to examine the stump and found it to be perfect in every detail.

Case VII.—R. H., thirty-two years of age, was admitted to the hospital May 5, 1903, with a spontaneous fracture of the tibia, caused by a rapidly growing sarcoma. On May 11 the thigh was amputated by Bier's method. (Fig. 3) Primary union resulted and patient was discharged cured June 7. Patient wears with perfect comfort an end-bearing artificial prothesis; the stump has not atrophied, and is neither painful nor tender in the slightest degree. In the skiagraph of the case there is to be noted the large amount of callus between the apposed bone surfaces.

Case VIII.—J. K., twenty-three years of age, was admitted to the hospital September 27, 1903,

Fig. 3.



Osteoplastic Amputation of Thigh.

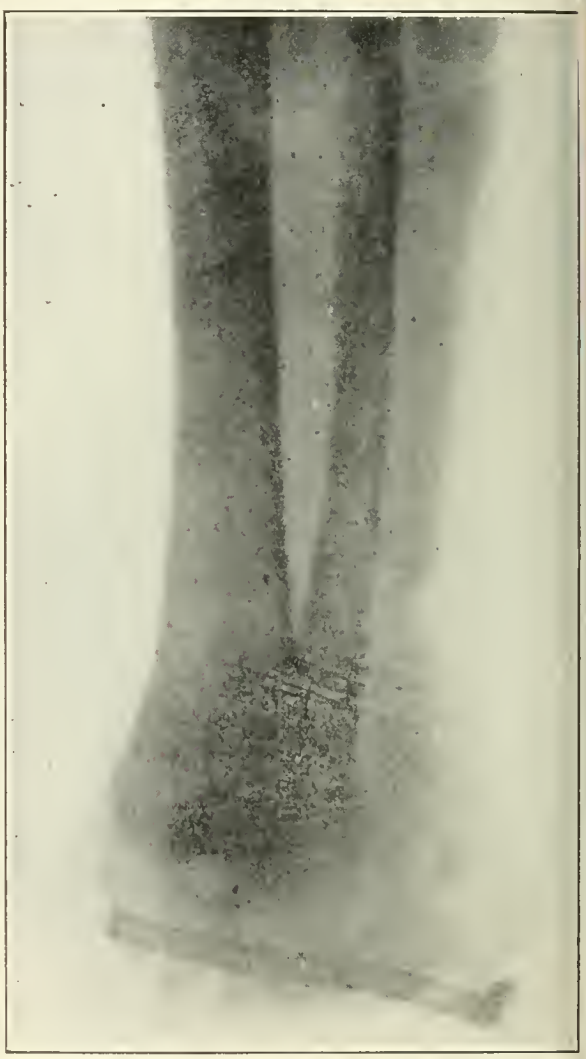
with an extensive deformity of the left foot, due to trauma. On October 2 the foot was amputated at the ankle-joint, by an osteoplastic procedure, the various steps of which are described in the *Annals of Surgery* of May, 1904. (Fig. 4) Patient was discharged cured January 17, 1904. The stump is perfect in every detail, and patient wears an artificial prothesis, which is only very little different from an ordinary shoe.

The main object of this article is to prove the superior advantages of amputation stumps formed by osteoplastic methods, as opposed to stumps formed by the older methods; but in order to do so understandingly, it is necessary that I digress for a moment, and discuss, if ever so briefly, the physiology and pathology of amputation stumps.

Strictly speaking an amputation stump has no physiological function in itself; whatever physiological function is ascribed to a stump is done only by the addition of an artificial prothesis, which is to act as a substitute for the amputated portion of the extremity. By the addition of such artificial prothesis the important physiological functions of "support and locomotion" are derived.

If the normal physiological function of an amputation stump is of importance, a disturbed physiological function is of still greater moment to individuals who have been unfortunate enough

Fig. 4.



Osteoplastic Amputation at Ankle-joint.

to require an amputation; and as all amputation stumps, performed no matter upon which part of any extremity, may become pathological, it is important to pay just as much attention to stumps of the upper extremity as to those of the lower extremity. It is not my aim to weary you with a detailed description of the various pathologico-anatomical conditions to which amputation stumps are liable; suffice it to say, for our present pur-

pose, that there are certain symptoms common to all, and the most important of these is, pain or tenderness, or both. The importance of these two symptoms is due to the fact that it is their presence which prevents the respective amputation stumps from fulfilling their normal physiological functions of "support and locomotion."

To recapitulate, therefore, it might be said, that a stump is perfect and to be looked upon as normal, only when it is fully able to carry on its physiological function of support and locomotion; every other stump, which does not or cannot conform to these requirements is abnormal and pathological.

One would think that these simple facts ought to be universally accepted as true, particularly when it is considered that the operation for ablating an extremity is one of the oldest known to surgery; but this is not the case; on the contrary, the opinion was prevalent that there are certain ills inherent to amputation stumps, which must be accepted as one of the evil consequences of the operation. It is practically only within the past decade that the dawn of a new era began to assert itself, and more and more attention is beginning to be paid to a good physiological function of the stump.

The question arises, therefore, which one of the various structures which enter into the composition of a stump forms the deciding element as regards its good or bad function; as it is only by knowing this element that we can take steps, either for its preservation or exclusion. Every one of the more important structures, which enter into the formation of a stump have at one period or another been blamed; it is necessary, therefore, to critically examine all, viz.: (1) The integument; (2) muscles, tendons and fasciæ: (3) the nerves; (4) the cicatrix; (5) the bone and periosteum.

1. *The Integument.*—For a long time the skin which covers the stump was looked upon as the most important factor; and many operative incisions were designed, mostly with the object in view to obtain the most suitable integument for covering the stump. It was particularly stated that only such skin can be utilized effectively which is designed by nature for pressure; to prove the fact that only such skin can be utilized effectively, there were pointed out the good function of the well-known Pirogoff and Gritti stumps, in the former of which the integument covering the stump being taken from the thick skin of the heel, and in the latter from the thick skin covering the patella; the good function of these stumps, however, as will be shown later, depends wholly upon a different principle. Furthermore, it has been repeatedly proven, that stumps in other respects well made, but covered with the thinnest and most delicate skin (*e.g.,* in one case of Bier from the thin skin covering the tendon of Achilles), will be able to withstand the greatest pressure; and in addition it has also been found that every skin, provided the function of the stump is good, will eventually hypertrophy, so as to resemble skin designed by nature for pressure. In one of my cases (amputation at the middle of the leg) the skin is so thick as to make an unsightly, but nevertheless perfect stump as far as function is concerned. We must, therefore, arrive at the conclusion that the integument is not the deciding factor.

2. *Muscles, Fasciæ and Tendons.*—Another structure which engaged for a time the attention of surgeons was the musculature covering the stump; and the theory was propounded, that a stump in order to be functionally good must be liberally covered with heavy muscles, which would act as a buffer. This gave rise to a number of operative procedures (particularly the transfixion methods), all designed with the object in view to cover the end of the stump with large and heavy muscles. The results were stumps beautiful to look at when of recent origin, but in the course of time this also proved to be futile, as it was soon found that even with heavy muscular cushions, pressure, particularly if continued for a long period, soon became unbearable; and in addition all the muscles very soon atrophied, the atrophy persisting in spite of energetic massage, the use of electricity, etc. This occurrence is well known to everybody; there is no necessity, therefore, to bring many examples; it is only lately I have had occasion to examine a stump of the thigh in an adult, the muscles of which were so atrophied that the diameter at the middle of the thigh was only two inches, and the end of the stump was so tender that the patient winced with pain at the slightest tap of the finger.

This muscular theory is disproven also by the fact that there are in existence a number of amputation methods (*e.g.,* Stephen Smith, Pirogoff) in which there is not a trace of muscle covering the end of the stump, and yet functionally these stumps are simply ideal. What has been said of the muscles is equally true of the less important structures of tendons and fasciæ. I am fully aware that the only lately Dietel (*Deutsche Zeitschrift für Chirurgie,* February, 1904), published a few good results, which were obtained by covering the stump with tendons, but my experience will not bear this out.

3. *The Nerves.*—The nerves in a stump have engaged the attention of surgeons for a very long time, and in a measure with more right than any of the structures yet mentioned, because one of the diseases to which the stumps are peculiarly liable, depends particularly upon a pathological condition of the principal nerve trunks. It has been known for a long time that nerves divided in an amputation, particularly when they become adherent to the resulting cicatrix, are very prone to develop painful neuromata, and even were the stump functionally perfect in other respects, the presence of such a neuroma would be amply sufficient to frustrate its perfect physiological function. In a majority of instances, however, the prophylaxis of such an occurrence is readily at hand, as all that is necessary is to carefully isolate the nerve trunk during the operation, to draw

it out as far as possible, and to divide it at a higher level. In a few rare instances a painful neuroma develops in spite of this procedure, and for the cure of these cases Bier has proposed a neuroplastic suture to be carried out on the principle of his osteoplastic procedure. Personally, I have also seen a few pathological stumps, which were due in part to a fault of the divided nerves, and their occasional occurrence cannot be denied, but the greatest majority is certainly due to other causes.

4. *The Cicatrix.*—It is a well-known fact that scar tissue is less resistant and more tender than normal tissue; this is very probably due to an enclosure of the finer sensory nerve endings, and their compression by the natural contraction of the cicatrix. The cicatrix was therefore looked upon as one, if not the main, cause of painful and tender amputation stumps; nor can it be denied that there were certain grounds for this supposition. Acting upon this theory, in order to avoid any exposure of the cicatrix to pressure, numerous incisions were devised, mostly of the variety of two unequal flaps; these when sutured, placed the resulting scar to one side of the end of the stump, where it naturally was less liable to pressure than if placed directly upon the end of the stump.

This, as one might say, physiological property of cicatricial tissue must and should be taken into account as far as possible in all amputations, but it should never be of sufficient importance to sacrifice any of the length of the stump to it, because it applies more particularly only to the massive cicatrices of secondary union; the non-adherent linear cicatrices of primary union either do not have this quality at all, or to so slight an extent, that for practical purposes it may be entirely disregarded. I have personally performed amputations, the stumps of which were perfect as far as end-bearing function was concerned, in spite of the fact that the scar was placed directly upon the end of the stump. We can safely say, therefore, that the presence of the scar is not the deciding factor in the proper construction of amputation stumps.

5. *The Bone and Its Periosteal Covering.*—These are the structures which I believe to be of the greatest importance, and which must be discussed at somewhat greater length. It would be altogether erroneous to believe that end-bearing stumps are an innovation in surgery; on the contrary several were known for a long time, but they were not properly interpreted. The simplest of these were the pure exarticulations; it was universally acknowledged that the exarticulation stumps formed in a pure and unadulterated fashion functionated perfectly; but they were erroneously interpreted, as on their account the theory was propounded that only such amputations were followed by a good result which were performed through the comparatively broad epiphyses. That this was an error and misleading in many ways is well evidenced by the fact that there are many amputations in which the section of bone is carried out through the broadest kind of an epiphysis, and yet the functional result is poor. And still amputations of this nature are highly commended in all text-books.

Permit me to call your attention here only to the well-known Carden amputation through the condyles of the femur. In this operation, the section of the bone is carried through the massive and broad condyles of the femur. Good function is claimed for the Carden stump, because "its extremity is well calculated for sustaining pressure, both on account of the breadth of the cut surface of the bone divided through the condyles, and from the character of the skin habituated to similar treatment in kneeling." (The Operations of Surgery, Jacobson and Steward, Philadelphia, 1902). Koenig (Lehrbuch der speciellen Chirurgie) also praises the exarticulation, but in comparing the exarticulation with the transcondyloid amputation, says that the latter often does as much as an exarticulation, as it offers the patient a point of support, upon which he can press directly with a prothesis. Both from experience and on account of theoretical reasons I would be inclined to doubt the great value of this operation. My personal experience with it is limited to the following case:

Case IX.—O. S., fourteen years of age, was admitted to the hospital May 8, 1899. Patient had a very large sacral myelomeningocele, and as a result of this was suffering from paralysis of the lower extremities, with extensive trophoneurotic ulcerations. On account of the extreme deformity an amputation at the knee was decided upon, and was performed May 22, on the left side, and June 12 on the right side, by the Carden method. Primary union resulted and patient was discharged July 26.

Patient presented himself for re-examination April 10, 1904, and I found a peculiar deformity of both thighs, inasmuch as both were rotated inward to an arc of 90 degrees. Linear scars on both amputation stumps; no pressure could be exerted on the end of the stump, on account of extreme tenderness, though it must be admitted that pain was not present.

In this case surely the function was anything but good; pressure upon the end of the stump was not born properly.

On the other hand, I may go one step further and review also the indications for this operation. I know of no disease where a Carden operation would be absolutely indicated, more particularly in view of the fact that we are in the possession of an amputation method at the knee-joint which gives the very best functional result, and which withal is safer, simpler, and consumes less time for its execution. The operation I refer to is a pure and simple exarticulation, without interfering in any way or manner with the articular surface of the femur. I have had occasion to operate but one case in this manner and I can assert without the slightest hesitation that both the primary and ultimate results were simply perfect.

Case X.—P. L., thirty-nine years of age, was

admitted to the hospital May 20, 1903, with a progressing gangrene of the foot due to arteriosclerosis. May 22 a typical exarticulation at the knee joint was performed; primary union resulted and patient was discharged cured June 4.

Contrasting the two cases just related, and for reason which will become more apparent in the course of my paper, I believe I am entitled to formulate my opinion as regards these two amputations in so far that the Carden as such should be abandoned, and in its place there should be substituted the simpler, safer and better exarticulation. (It is only proper to mention here, that the functionally perfect Gritti and Ssabanejeef operations will be discussed later.)

Another well-recognized and universally adopted method of amputation, which can be brought up to refute the theory that amputations performed through broad epiphyses are always followed by good functional results, is the Syme's amputation. As is well known, in the original Syme operation the section of the bones is carried through tibia and fibula at a level slightly higher than the cartilage covering the tibia; later modifications leave in site the cartilage covering the tibia, and saw off the two malleoli only; and good results have been claimed for this amputation. Personally, I have had no experience whatsoever with either the original Syme operation or with its later modifications, but through the courtesy of the firm of A. A. Marks, manufacturers of artificial prothesis, I have had occasion to examine a number of Syme stumps, and I have invariably found marked tenderness present. On this account and also on purely theoretical grounds I cannot agree with the views given, and instead I have devised a new amputation in the region of the ankle joint, based on a different principle, which at least in the case tried (Case VIII) has given me a perfect result; an account of it has appeared in the May, 1904, number of the *Annals of Surgery*.

In refutal of the theory of epiphyseal amputations we can also bring up the well-known Pirogoff amputation. This, as is universally conceded, forms an excellent stump, and yet its distal end formed as it is only by the posterior extremity of the os calcis, is no broader than the diaphysis of the tibia or femur. These various examples are, I believe, sufficient to prove that the theory of epiphyseal amputations is not tenable.

Another amputation which was well known, in fact so well known that it has received the rather flattering name of "amputation at the seat of election," is the one in the upper third of the leg. This amputation was particularly preferred prior to the present perfection of artificial prothesis, because the stump was bent at the knee, and the anterior surface of the tuberosities of the tibia was fitted into the socket of the artificial pegleg. In view of the fact that the stump, so bent, could very well stand the pressure of the pegleg, and never gave rise to any trouble, the theory was propounded that the stump in order to give perfect function, must be covered by skin designed by nature to pressure, and which must be in original connection with the underlying periosteum and bone. This no doubt also served as the underlying principle upon which Ssbanejeef designed his ideal and perfect amputation at the knee-joint.

But let us investigate a stump formed at the so-called seat of election; it is soon seen that the end of the stump, which after all is the point to look at, does not enter into function at all, as it is situated some distance behind the point of support; as a matter of fact this end of the stump in ninety-nine out of a hundred cases is absolutely poor, and will not stand the slightest amount of pressure; and the ability to wear with a certain amount of comfort an artificial pegleg in these cases does not depend in the least upon the stump. It is seen therefore that this theory also is untenable.

Just a word here regarding the functionally excellent Gritti amputation, as in it there are present all the conditions which are required to correspond with the theory above stated, viz., the skin covering the end of the stump is that normally covering the patella, is designed by nature to pressure, and furthermore is still in connection with the underlying periosteum and bone. It is true that this stump is perfect, but personally I believe and know that the good function of this stump depends wholly upon the patella, and I also believe that the function of the Gritti stump would be just as good if the skin covering the patella were all destroyed, and in its place, integument from the lateral or posterior surfaces would be utilized for covering the stump. The perfect function of the Gritti stump cannot be denied, but in view of the fact that an exarticulation at the knee joint is just as perfect, simpler and quicker, it is questionable whether we shall find many indications for its performance; perhaps it should be reserved for those comparatively rare cases only in which the patella is healthy, but the articular surfaces of the femoral condyles are diseased.

For a while considerable stress was laid upon the periosteum covering the bone, and numerous methods were, and for that matter still are, in vogue, which laid particular stress upon the preservation and subsequent suture of a cuff of periosteum. In spite of numerous assertions to the contrary, I have personally never seen any permanent benefit to arise from such a procedure, as, peculiar as it may appear, the periosteum so sewn over the end of a sawn surface does not form new bone, as one might be inclined to expect. I have frequently had occasion to examine stumps formed in this manner at secondary operations and with the Roentgen rays as well, but I have never seen any new formation of bone.

Let us now go backward a few years, say 1897, and ask once more, what was the state of our knowledge regarding the good function and painlessness in general of amputation stumps? We can sum up our knowledge in brief in the following: absence of pain and good function was present only (1) in all typical exarticulations, (2)

in the Pirogoff amputation, (3) in the Gritti amputation, (4) in the Ssabanejeef amputation, and (5) in the Scymanowsky amputation. This was the state of affairs when Bier began his studies upon this very important point, and the question therefore was only to find out the one common thing, the presence or absence of which is to decide the good or bad function of the stump. As a result of his studies and experiments Bier (Sammlung klinischer Vorträge No. 264) arrived correctly at the conclusion that "in none of these amputations does the bone expose a wounded surface," and in consequence he has been enabled to propound an entirely new theory regarding the good function of amputation stumps, viz., "that in no case must the bone expose on its distal extremity a wounded surface; and in order to obtain this result, it is necessary to cover or seal the wounded surface with bone covered by its periosteum, or if this be impossible, it is preferable to exarticulate."

This was the fundamental principle laid down by Bier for all amputations, and to carry it out he devised the now well recognized method, which is known as the osteoplastic amputation. This is not the place to discuss the method in detail, as it has been done so frequently that it would be merely needless repetition. The underlying principle is to form, either from the bone amputated or from a neighboring bone, a thin osteoperiosteal flap, which obtains its mobility from a hinge of periosteum; this osteoperiosteal flap is brought into correct apposition with the sawn surface of the amputated bone, and its periosteum is sutured to the opposed periosteum and to other convenient structures. If the work is done under aseptic conditions primary union usually results, and when this is the case, it has been my experience that the final outcome is perfect in every instance.

Just one word more regarding the indications for this operation; as a general rule it might be said, that it is indicated in every amputation, in the upper extremity as well as in the lower, with the exception of the following two, first, in all those cases in which the general condition of the patient demands a hasty termination of the operation, and second, in those cases in which the nutrition of the parts (diabetes, syphilis, etc.) is so poor that there is danger of necrosis of the osteoplastic flap.

In discussing the question of indication it will not be devoid of interest to critically examine my cases in this respect; both the primary and ultimate results must be accounted for. If this is done it will be seen that one case (Case III) died, that in two cases (Cases II and V) the osteoperiosteal flap had to be removed, in the remaining cases both the primary and ultimate results were ideal. In the case with the fatal outcome, death, as already stated, was due to insolation, and this occurrence could have happened just as well after a simple amputation, or any other operation; certainly blame for its occurrence cannot be attached to the particular method of operation performed.

The osteoperiosteal flap had to be removed in two cases. In Case II a Pirogoff amputation was performed at the express request of the patient for a low amputation; owing to the poor vitality of the tissues, due to an extreme endarteritis, the bone flap necrosed and had to be removed; but this is no fault of the method, an error of judgment occurred, as only an amputation at a higher level should have been attempted. In Case V a slight marginal necrosis of the bone flap took place; in due time the involved portion would have exfoliated, in no way marring the ultimate result; owing to advanced metastases it was deemed best to hasten the closure of the sinus by removing the flap.

I am firmly convinced that the osteoplastic method of amputation forms one of the greatest advances of modern surgery; and I believe it to be worthy of more extended trial than has been heretofore vouchsafed to it.

NEED OF MORE ACCURATE KNOWLEDGE IN THE DIAGNOSIS AND TREATMENT OF CHRONIC SUPPURATIVE OTITIS MEDIA.[1,2]

BY JAMES F. McCAW, M.D.,
OF WATERTOWN, N. Y.;
OCULIST, AURIST AND LARYNGOLOGIST, CITY HOSPITAL AND JEFFERSON COUNTY ORPHAN ASYLUM; FELLOW OF AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY, ETC.

THE subject of chronic aural suppuration has been suggested to the writer by the number of cases seen each year, in which the diagnosis and treatment have been matters of indifference, and in many cases the possible significance of the symptom entirely overlooked.

The importance of this condition and the early application of appropriate treatment should be fully appreciated by every practising physician. In spite of the many articles and discussions upon the subject, there are physicians who fail to appreciate the importance of aural discharge, and allow children entrusted to their care to suffer irreparable damage to an organ of inestimable value from an educational, as well as from a sociological and economical standpoint. How often, I am sorry to say, do we hear the advice given that it is nothing but a "running ear," wash it out once in a while and the child will outgrow it? *The number of cases in which the disease outgrows the patient will never be known, for I venture the opinion that many die from intracranial complications in which the chronic suppurative middle-ear disease is never recognized as a causal factor.*

Many physicians regard chronic otorrhea much too lightly, and frequently consider it a mere inconvenience, instead of giving it the proper consideration as a serious condition, from which grave complications may arise at any time.

It must be admitted that there are many cases of chronic aural discharge which pass a long life without suffering any apparent inconvenience, ex-

1 Read before the Medical Society of the State of New York, January 27, 1904.
2 Received for publication May 6, 1904.

cept from the presence of the discharge, and die from some intercurrent disease. These cases occur in every physician's practice.

On the other hand, we must not lose sight of the fact that this disease progresses insidiously, destroying the delicate structures of the middle ear, invading the bony walls, impairing their nutrition, subsequently ending in caries or necrosis. An extension to the mastoid, antrum or cells may take place, and finally a serious invasion of the intracranial contents may occur. There is no good reason to suppose that one case will pass through life without further trouble, while another, with practically the same local conditions, will develop serious complications. Until we are able to separate these cases, I contend it is the duty of every physician to bear in mind the grave consequences that follow a neglect of this condition.

It is unfortunate that these vast and destructive changes often take place without pain, and that the gravity of the affection is not always commensurate with the symptoms. When pain does supervene upon a chronic discharge it is of great significance; it is nature calling out for relief, and warning us of disastrous results likely to follow if the warning is unheeded. For a physician to stand by and wait for the catastrophe of which he has been forewarned is little short of criminal negligence. At the outset every case of chronic suppuration of the middle ear intrusted to our care should receive a most careful examination of the nose and nasopharynx to determine their condition and the possible influence of obstructive lesions in these localities. All such obstructions are now well recognized factors in the persistence of chronic ear discharge, and as influencing a recurrence. They should be removed when found to exist in either locality.

It seems almost superfluous for me to add that adenoid growths of the pharynx is a most common and fruitful cause of aural suppuration. Nevertheless, there are still physicians who will not, or at least do not, appreciate the importance of this relation, and utterly fail in the treatment of these cases by lack of a thorough investigation and recognition of the possible causal factors. It is sometimes remarkable what rapid improvement will take place in a persistent and intractable discharge by attention to this most important part of the treatment. This is especially noticeable in children and young adults.

The next important step in the investigation is to determine the location of the perforation and extent of destruction of the membrana tympani, and whether or not thorough drainage is taking place. Chronic suppurative disease in this cavity, when dependent upon insufficient drainage, should be treated on general surgical principles, the same as it would be in any other cavity of the body; that is, by free incision and removal of any obstruction so as to allow thorough drainage and promote healing. Where is there a general surgeon or gynecologist who would treat an insufficiently drained pelvic abscess discharging into the vagina by simply ordering a cleansing vaginal wash, and that without investigation to determine the source or cause of the trouble, subjecting his patient to the number of serious consequences that may follow? I venture to say there is not one who would be guilty of such lax methods in the treatment of so important a condition. There are, I am sorry to say, numberless cases of chronic aural discharge treated in just this manner; the extent and cause of the local condition not having been investigated by the attending surgeon, putting the entire responsibility upon nature and trusting to good luck that the patient may escape subsequent complications. To some this may seem overdrawn, but to those working in this field their experience, I am sure, will substantiate it as a true picture.

When we come to consider the prognosis in these cases we realize how important it is to know what structures of the middle ear are involved and the extent of such involvement. At our first examination we should ascertain the location of the perforation, if caries of the ossicles or adjacent structures exist, if polypoid degeneration is present within the tympanum, if there are cholesteatomatous changes, and, finally, if the process is limited in its destruction to the middle ear. It behooves not only every aurist, but the general practitioner as well, to appreciate the importance and significance of this knowledge as bearing upon the care and proper management of chronic ear discharge. A perforation situated high up in the drum usually signifies necrosis of the ossicles, or involvement of the attic structures and less tendency to kindly healing. Necrosis or polyps when present must be removed, and granulation tissue destroyed before palpable results can be expected. Cholesteatomatous complication or an extension of the process beyond the confines of the drum cavity, indicate a much more serious condition and call for radical interference, as these patients are drifting beyond the border line of safety into the field of meningeal complications. I ask, then, is it reasonable to suppose that chronic middle-ear suppuration can be treated intelligently without such knowledge?

Every thinking physician knows that to treat these cases empirically is not in accord with the present advanced knowledge of the pathology of disease. To persist in these lax methods is to close our eyes to the light of medical and surgical advancement, and to result detrimentally to the patients entrusted to our care. The treatment of any disease must be based upon the broad and fundamental principles of pathological anatomy. These principles, as applied to the disease in question, are of paramount importance on account of the intimate anatomical relation of the middle ear to many vital structures. When the profession as a whole begins to realize that aural suppuration means more than the mere presence of a discharge, and that patients suffering from this condition are prone to many and serious complica-

tions—then, and not until then, will chronic suppurative otitis media be treated with a full appreciation of its possible gravity.

In this paper there is no claim made to originality; it is merely the presentation of a few facts concerning the diagnosis and treatment of a disease which in many instances have been neglected, and a plea to the profession in general to attach to this disease its proper significance, and not look upon it as a condition unworthy of a most careful examination and investigation into the cause and extent of the trouble, a procedure which will manifestly give a more rational basis for treatment. It is only by keeping these facts constantly in mind and dealing with every case accordingly that we can expect a cure of a chronic otorrhea. We would be sorry to be understood as advocating radical surgical measures in every case of chronic otorrhea; but we do insist that every case should receive its appropriate treatment according to the pathological condition present, and all physicians under whose care these cases come should obtain this knowledge before attempting treatment.

The writer has purposely omitted the question of prophylaxis, for, although a very important and interesting phase of the subject, to deal with it would carry us far beyond the limits of this paper.

DEDUCTIONS.

1. Chronic otorrhea is not given the importance that its gravity demands.

2. In all cases the treatment should be based upon the pathological condition present.

3. In addition to proper attention to the nose and nasopharynx and all minor surgical procedures, appropriate treatment to the middle ear will yield good results in a large percentage of cases.

4. Where caries is limited to the ossicular chain and there are no contra-indications, ossiculectomy should be the operation of selection.

5. Cases presenting symptoms of extension beyond the tympanic cavity should be subjected to the radical operation.

INTESTINAL OBSTRUCTION FOLLOWING APPENDICITIS OPERATIONS. REPORT OF EIGHTY-SIX CASES.

BY CLARENCE A. McWILLIAMS, M.D.,

OF NEW YORK;

INSTRUCTOR IN SURGERY, COLUMBIA UNIVERSITY; SURGEON TO TRINITY HOSPITAL; ASSISTANT SURGEON TO PRESBYTERIAN HOSPITAL.

The literature on the subject of appendicitis has reached enormous proportions, and on first sight it would seem that all has been said which could be said without needless repetition. One aspect of the subject, however, has not been sufficiently emphasized. It is the disastrous number of sequelæ which may result from an appendicitis which has gone on to the formation of an abscess, either within or outside of the appendix. A partial list of those most frequently occurring is as follows: Lymphangitis, lymphadenitis, especially of the mesenteric and retroperitoneal glands; venous thrombosis of the right or left iliac and portal veins, Douglas' and tubo-ovarian abscesses, psoas abscess, lumbar abscess, perinephritic abscess, subphrenic abscess, septic hepatitis, hepatic abscess, septic cholangitis, septic cholecystitis, septic pneumonia, abscess of the lung, empyema, pancreatitis, septic ulcer of the stomach with hematemesis, fecal fistula, intestinal adhesions, bands and obstructions, post-operative hernias, ureteral obstruction, pyemia, inflammation of the parotid gland, ischio-rectal abscesses, rupture of abscesses into cecum, colon, rectum, or bladder, secondary hemorrhage from the artery of the appendix, circumflex iliac artery, or iliac vein, acetonemia, etc.

Surgeons thoroughly appreciate the dangers of waiting before operating in cases of appendicitis, and their zeal in the matter of early operation has often been wrongly attributed by their medical confrères to operative enthusiasm. Evidence, however, is rapidly accumulating to convince the most incredulous that their position is a most sound one, based on both clinical and pathological findings. In this list of sequelæ, perhaps no single one is more to be dreaded than intestinal obstruction. This condition is the result chiefly of the delay for what is commonly known as "walling off," which means the waiting for the abscess to be surrounded by adherent intestines. No one can tell when these adhesions may produce intestinal obstruction, and surely in any disease we must take into account just as much the remote results as the immediate ones. We may also say without fear of contradiction that there has been a time in every fatal case of appendicitis when an operation would have saved the patient.

In a study of 1,000 operations for acute intestinal obstruction and gangrenous hernia made by Dr. Charles L. Gibson (*Annals of Surgery*, Vol. 32, Nos. 4 and 5), he found "bands" to be the cause of obstruction in 186 cases, this being the commonest form of acute obstruction in the adult. "These were most frequently from inflammatory remains of appendiceal troubles and from the female pelvic organs. While the subject for simplicity's sake is treated under the heading of bands, it must be borne in mind that many of these are in the form of diffuse, velamentous adhesions, causing obstruction by kinking and knotting of the intestines, as well as by direct diminution of the caliber of the intestine, and strangulation of the blood-supply."

Fifty-eight per cent. of these 186 cases were in males; and the site of the obstruction was the small intestine in eighty-six per cent. of all the cases.

In taking up this subject, I shall first report *in extenso* two of my own cases, one of which had two post-operative attacks of intestinal obstruction successfully operated upon, the second case having eighteen inches of gangrenous intestine. Following this are all the cases which I have been able to find in the literature on the subject. In addition, there will be found a number of unpublished cases, occurring in the practices of various

surgeons who have been kind enough to allow me to publish them. Lastly, there will be found a general discussion of this vital and interesting topic.

E. L., female, single, Russian, cirgarmaker; admitted to the Presbyterian Hospital, September 11, 1903, with the following history: Family and previous history negative in every respect. Present trouble began two days prior to her admission, when she was suddenly seized with sharp pain in the epigastrium, accompanied with vomiting. The next day this pain localized itself in the right iliac fossa, where it became exceedingly tender. Vomiting continued occasionally with nausea until admission. Bowels moved normally. On admission, temperature was 101⅘° F.; pulse, 120; respiration, 32. Patient is pale, anemic. Whole abdomen is tender and somewhat distended, and moves but slightly with respiration. Tenderness most marked in right iliac fossa, where there is very great muscular rigidity, which makes the detection of a possible underlying mass impossible, although it was supposed to exist.

Immediate Operation (gas and ether being employed).—Intermuscular incision with blunt separation of the muscles in the direction of their fibers. Appendix found retrocecal, surrounded by a pocket containing about two ounces of thick pus, swollen to the size of one's thumb, and intensely congested. The base of the appendix was gangrenous with a perforation about half an inch from its insertion into the cecum. Double ligature of plain catgut applied to its base, which was cauterized after amputation of the organ. No irrigation used. Two small drains of gauze, wound about with rubber tissue, were passed down to the appendix site. Remainder of wound closed with catgut in layers. Time, thirty minutes. Condition postoperative, good. After the operation all the symptoms became ameliorated. Temperature and pulse gradually lowered. On September 18, eight days after operation, highest temperature 101.5° F.; pulse, 85.

On the ninth day, the temperature suddenly dropped from 101° to 97° F., and the pulse became 100. Patient complained of cramp-like abdominal pains and began to vomit. On the tenth day symptoms referable to the abdomen were better until the night of the second day of her pain, when her condition became more serious. At midnight the temperature was 96° F.; pulse, 120. The vomiting was frequent and very foul, abdomen distended, but not at all tender. Numerous high enemata failed to bring away any fecal material or gas. Early in the morning of the third day, the eleventh day after the first operation, the vomiting became fecal, entirely unrelieved by lavages, and there had been no bowel movement. The abdomen was more distended, with slight general tenderness. Vigorous peristaltic sounds could be heard all over the abdomen with the stethoscope, and there was almost no muscular rigidity. From the lack of rigidity and marked tenderness, and the presence of vigorous peristalsis, it was evident at once that we had to deal with a mechanical obstruction, and not an inflammatory one. The pulse was poor and 130.

Operation, September 21, 1903, 10 A.M. (gas and ether).—Median incision above the pubis. Much distended small intestines presented. Pads inserted, drawing the intestines over toward the left iliac fossa, so as to give a clear view of the appendix region, where it was surmised the trouble lay, and so it turned out to be; for it was seen at once that the two extremities of a single coil of small intestines were adherent to the abdominal wall in immediate juxtaposition to each other. The portion of the coil distal to the adhesion had become twisted upon itself, completely obstructing its lumen; for the portion of the intestine leading up to the point of adherence was ballooned to the size of one's arm, while the coil leading away from the adhesion was completely collapsed. As soon as the twist was undone, the gas passed on rapidly into the collapsed intestine. One extremity of the twisted coil was loosened from its adhesion to the abdominal wall, and an area on its surface, denuded thereby of its serous coat, was closed in by a Lambert suture of fine silk. The other extremity could not be loosened on account of the firmness of the adhesions, so it was left as it was. Patient in bad condition, requiring an intravenous infusion of salt solution. Rapid closure of the abdomen by silkworm-gut sutures passed through all the layers. Five dejections followed the operation the same day without any artificial assistance. Vomiting ceased a few hours after the operation. Pulse the next day 100 and the patient very comfortable, the temperature being 100° F. No distention.

The subsequent course was uneventful until the midnight of October 6, 1903, being the twenty-fifth day after the first operation, and the fifteenth day following the second one. She then began to vomit large amounts of undigested food. Vomiting continued the next day, unrelieved by repeated lavage. Enemata failed to evacuate gas or fecal matter. During the day the abdominal signs developed exactly as they had in the previous attack of obstruction.

Operation, twenty hours after the onset, October 7, 10 P.M.—Previous median wound reopened without cutting. Distended small intestine presented. A less distended loop was followed down in the direction of increasing distention and resistance until a point was reached where the coil was tightly adherent to a neighboring loop. This had produced a kink in the afferent loop, causing absolute occlusion of its lumen. Beyond this adhesion, the intestine was collapsed. The adhesion between the loops was separated, leaving a raw area on each loop the size of a quarter of a dollar. Gas passed immediately onward into the collapsed bowel. The raw areas on each loop were covered in with interrupted Lembert sutures of silk. No further raw areas were discovered after search. Relief was almost immediate after the operation. She vomited twice very foul material. There were three stools in the course of the following fifteen hours, and all pain ceased. Complete con-

valescence followed without a setback. The patient left the hospital on November 8, 1903, fifty-eight days after the first operation, forty-eight days after the second one, and thirty-two days after the third operation. On December 26, 1903, the patient was seen, and said she was in the best of health and had no digestive disturbances, bowels constipated. She was instructed to return immediately to the hospital on the appearance of any symptoms of obstruction.

The second case is as follows: Mrs. N. C., aged twenty-eight years; admitted to the Presbyterian Hospital, October 3, 1903, 11 P.M., with the following history: Three years ago operation in Philadelphia for appendicitis, two rubber tubes being left in as drains. Never any other serious illness. Seven weeks previous to admission, miscarriage, for which curettage was performed. Convalescence uneventful.

Three days before admission patient was seized with severe burning pain in abdomen, which was not localized but general. It was often very colicky. Later it seemed to be most intense in the lower median part of the abdomen, where it became very tender to the touch. Prostration soon became marked. She vomited constantly, and for four days there had been no movement of the bowels nor passage of flatus. Examination elicited the following points: Hippocratic facies marked, tongue dry, foul, coated with brown fur. Odor of breath foul. Temperature, 104.8° F.; pulse, 140, poor quality but regular. Heart and lungs normal. Abdomen distended and moved scarcely at all with respiration. Over the appendix region is a four-inch scar, evidently the result of a suppurating wound. Great tenderness over whole of lower half of abdomen, most marked in right quadrant, where there seemed to be a soft, semi-elastic mass, the size of a grapefruit, very indefinite in its outlines but extending over to and beyond the median line, and down behind the pubis. There was a tympanitic note over the whole of the abdomen, and over the mass. Very faint peristalsis heard over the abdomen with stethoscope. Vaginal examination elicited in the right fornix a tender, soft, rather elastic, indefinite mass bulging down behind the uterus. Profuse leucorrheal discharge. There was evidently peritonitis present with intestinal obstruction, the etiology of which could not be determined. It was thought possibly to be due to an appendix abscess which had ruptured, but the more probable diagnosis was ruptured pyosalpinx.

Operation, October 3, 1903, 1 A.M. (gas and ether being used).—Three-inch median incision above the symphysis. Free, foul-smelling purulent fluid escaped on opening the peritoneal cavity. Omentum adherent to uterus and tubes. On separating this, a coil of distended, blackish, small intestine presented, the two extremities of the coil leading over to the appendix scar, where they were adherent to each other and to the anterior parietes. About one and a half inches from the adherent point the coils had twisted about each other, producing an evident obstruction not only to the passage of the intestinal contents, but also to the vascular circulation; for, on attempting to lift up the gangrenous intestine, this broke away from its mesenteric attachment, practically of its own weight, and throughout the whole extent of the gangrenous area. There was no perforation anywhere, and the gut was distended. It lay almost wholly in the pelvis, the walls of which were covered with a foul exudate, in places necrotic. Resection of the gangrenous gut was performed as quickly as possible with a medium-sized Murphy button, and without the escape of any of the intestinal contents. Measurement of the part excised showed it to be eighteen inches long. The excess of mesentery was reefed with catgut. Peritoneal cavity irrigated thoroughly with profuse quantities of hot saline solution. No trace of the appendix was seen at any time of the operation. Two large cigarette drains left in the lower angle of the wound, which was hastily closed with silkworm-gut sutures, passed through all the layers of the abdomen by means of a handle needle. Patient in bad condition, making necessary a saline intravenous infusion of 1,500 c.c. at a temperature of 110° F. on the operating table.

Patient's condition remained grave after the operation, responding very slightly to all forms of stimulation. In the first twenty-four hours three hypodermoclyses of 1,000 c.c. of saline solution were given. There were also in this time four dejections as the result of turpentine enemata. Repeated lavage allayed the vomiting. Temperature next day was 105.5° F.; pulse, 140 and weak. Nutrient, stimulating enemata given. Patient died on the fourth day after the operation of progressive rapid sepsis, due to the purulent condition of the pelvic walls.

The following case occurred in the service of Dr. F. Tilden Brown, to whose kindness I am indebted for the privilege of recording it.

P. M., female, aged twenty-nine years; clerk. Four or five attacks of slight appendicitis. Admitted to hospital seventeen hours after beginning of present attack, on June 21, 1903, with a temperature of 101° F.; pulse of 90. Abdomen rigid all over, but this very marked in the right iliac fossa, where there was exquisite tenderness, but no mass. Intermuscular operation was at once performed. The appendix was intensely inflamed, and there was an ounce or two of pus about it. It was removed, and two small cigarette drains were left down to the stump, the wound being largely closed. Convalescence was smooth until the twentieth day, in the morning, when she was allowed out of bed for the first time. In the afternoon of that day, July 11, she complained of considerable pain in the abdomen, and vomited that evening and night several times. The next day the vomiting continued, and in the evening became fecal. No movement could be obtained by enemata and she became distended.

Operation at Midnight, July 12, 1903, two days after the onset of the first symptom (gas and ether).—Vertical incision through the right rec-

tus, whose muscular fibers were bluntly separated at the level of the naval. Serous fluid escaped from the peritoneal cavity, and there were many adhesions in the neighborhood of the cecum. A band of omentum was traced through the peritoneum and found attached to the muscles in the old wound. The intestines had evidently looped over this so that a volvulus had formed. The band was cut and the twist reduced, air passing immediately into the collapsed portion of intestine. Closed in layers, a small drain being left in the lower angle. Patient had a good bowel movement the next day, and all her symptoms subsided. She went home August 15, 1903, fifty-five days after the first operation, and thirty-three days after the second one.

We may divide the cases of obstruction occurring after an operation for appendicitis into three classes: 1. Immediate. 2. Early. 3. Late obstruction. The first class, immediate obstruction, comprises those cases in which obstruction comes on immediately after the operation, from a few hours to a couple of days. The operation is in many cases never quite recovered from before the symptoms of obstruction gradually present themselves. The obstruction here is usually due to intestinal paresis alone, caused by a local or general peritonitis; this paresis, however, may be accentuated by the effect of adhesions. Rarely at this time do we get the mechanical effect alone of adhesions. In some cases before the primary operation the arrest of the passage of the fecal material and of gas may project so prominently in the foreground that the erroneous diagnosis of intestinal obstruction alone may be made, and the appendicitis be overlooked.

The second class, "early" obstruction, is that occurring a number of days or weeks after the primary operation, before the convalescence from this is complete, usually before the complete healing of the wound. It may be due to two main causes: (*a*) The development of secondary abscesses in remote portions of the abdomen; the actual pressure of such an abscess may of itself produce obstruction, or the adhesions about such an abscess may produce angulation of the gut sufficient to obstruct its lumen. The simple opening of such an abscess has often resulted in the immediate subsidence of the obstructive symptoms. (*b*) The second cause in this class, and the more frequent, is that due to mechanical obstruction, produced by adherent loops causing constricting bands about each other, or resulting in angulation, volvulus, internal hernia, etc. It is not a question of present peritonitis.

The third main class, "late" obstruction, may come on weeks, months, or years after the primary operation, or even after an antecedent appendicitis, which has not been operated upon. During this period there may be perfect health without digestive disturbance of any kind, or there may be more or less stomach difficulty, and attacks of constipation. The causes of obstruction in this class are the same as under (*b*) in the second class.

The symptoms of immediate obstruction, arising as they do within a few hours or a couple of days after the primary operation, are often puzzling, for our treatment will depend on whether it be produced by paralytic ileus, due to peritonitis, either local or general, or to a mechanical obstruction, hence the importance of a correct diagnosis. In paralytic ileus we are apt to hear much decreased, or no peristalsis over the abdomen with the stethoscope; in mechanical obstruction it is strong and colicky. In the former we may get a history of the passage of some gas; in the latter the obstruction is complete. In the former, pain may not be great; in the latter it is violent and colicky, and not localized. Collapse comes on early in the latter, and is severer. Vomiting is not so apt to be stercoraceous in paralytic ileus and it is apt to be less projectile, less frequent, and less intractable. Muscular rigidity is much more pronounced and general in peritonitis than in mechanical obstruction. In the former the symptoms of progressive sepsis are more in evidence than in the latter.

The diagnosis between these two conditions, peritonitis or obstruction, is fraught with the greatest difficulty in the majority of cases, and is the cause of much anxiety to the surgeon. It is unquestionably true that many cases of mechanical obstruction have died unrecognized under the name of peritonitis. When in doubt, wait for a time the result of medicinal measures, *i.e.,* wash out the stomach with warm salt solution, putting in through the tube one drachm each of Rochelle and Epsom salts, which dose should be administered every hour until a result is obtained or a diagnosis is reached, employ high enemata containing olive oil and turpentine, or a solution of alum, which is often very efficacious, and give two or three hypodermics of atropine gr. $\frac{1}{200}$ at intervals of two hours. Atropine is given with the idea that it increases peristalsis and contracts blood-vessels, but it is useless, of course, if strangulation exists. Gentle abdominal massage may also be used. If these measures are not quickly followed by the passage of flatus or feces, and the possibility of mechanical obstruction still exists, operation had better be performed at once.

It must not be forgotten that mechanical obstruction and intestinal paresis (peritonitis) may coexist at the same time.

Operation being decided upon in immediate obstruction, what procedure is best? The mortality of these secondary operations, following closely a primary one, is frightfully high, due to the patient's prostrated condition. The quickest procedure, therefore, is urgently called for. A secondary abscess at a distance from the appendix site would call for an incision over its location. Barring this complication, we may reopen the wound, or make a median incision below the navel. Is the patient in a low condition, then the former procedure may offer the greatest hope. A loop of distended small intestine presenting in the wound is incised. If our opening be above the site of the obstruction, then the quantity of gas

and feces evacuated will be large, and can be increased by pressure on the abdomen, while neighboring coils of small intestine will collapse. In case our opening be below the obstruction, then we shall have to make another puncture in another loop. This procedure may likewise help in ileus depending on peritonitis alone.

In case the patient is in better condition, it may be wiser to quickly make a median incision in order to more thoroughly search for the obstruction. Evisceration may not be practised on account of increasing the shock. Peritonitis requires copious flushing of the abdomen with hot normal salt solution. Bands, etc., require appropriate treatment, while we may at times have to content ourselves with making an artificial anus, particularly in cases with general, extensive adhesions. Speed is a *sine qua non*.

2. "Early" obstruction as a rule presents little difficulty in diagnosis. The patient is convalescent from the original appendicitis operation and on regular diet, when there is a sudden attack of sharp, colicky, abdominal pain, with vomiting which is intractable, soon becoming stercoraceous. This colic is often due to error in diet, causing acute attack of indigestion. Obstruction of the bowels is complete, no flatus even being passed. The abdomen is not tender, nor is there much muscular rigidity, and this is true likewise when later the intestines beneath become distended. Rigidity only is present when peritonitis comes on. No tumor is palpable. Peristalsis is violent above the obstruction, and is heard loudly with the stethoscope. Shock is a prominent symptom, and the patient's condition becomes alarming, pulse rapid and weak, face very drawn and anxious, cold perspiration. The temperature drops to subnormal. The symptoms also may be subacute, due to the more gradual contraction of adhesions, or they may be coincident with the development of a secondary abscess at or far from the appendix site.

After a possible initial cathartic, no more should be given by mouth. Massage here is often very efficacious, because the adhesions are soft and yielding. High enemata, etc., should be tried, but as soon as a diagnosis is made, no time should be lost before proceeding to an operation, without waiting for the subsidence of the shock, which latter may never occur. A median incision is in order. A distended loop of intestine is sought for, and followed in the direction of increasing distention and resistance, until the obstructing cause is discovered, and appropriate treatment applied. Practically the small intestine is the one always obstructed, and the seat of the difficulty will be found in the right iliac fossa in the great majority of the cases. Secondary abscesses may be found buried deep in a mass of adherent intestines, necessitating drainage. Kinks are untwisted and angulations straightened, etc. Raw areas resulting from the separation of adhesions are buried under Lembert sutures, or covered with Cargile membrane. Gangrenous areas in the intestine resulting from volvulus, internal hernias, etc., are excised, and the ends either left in the wound, or brought together with a Murphy button. The abdomen is closed with the cavity full of salt solution, which may prevent the re-formation of some few adhesions. If the whole extent of the intestines is a great mass of inextricably agglutinated intestines, our only resort is to make an artificial anus.

Two measures besides high enemata, etc., may be employed to ward off an impending attack of mechanical obstruction, if used very early. One is vigorous abdominal massage. It is a very valuable procedure, and certainly has not received the attention it merits. The second is change in position of the patient, not only from side to side, but also particularly by elevation of the hips—this may straighten out a beginning flexure, and may change the direction of the peristalsis so that it will not impinge on a fixed point (Morris).

3. "Late" obstruction, as we have seen, may occur years after an appendix operation, so long previous that its connection with the present attack may not be thought of. It may occur also a long time after an appendicitis which has not been operated upon, for surely the adhesions may occur just the same without an operation as with one. This latter fact needs decided emphasis. The symptoms may be acute or chronic in character. The acute attack comes on without a premonition in a perfectly healthy person, either without any appreciable exciting cause, or after violent exercise, or a heavy, indigestible meal. It begins as a violent colic which yields to no treatment. Peristalsis is exaggerated, but ineffectual, as no gas nor feces are passed. Vomiting comes on at once and is persistent, sooner or later becoming fecal in character. Temperature remains normal for some time (may be subnormal from shock) until peritonitic inflammation arises. Shock is often a pronounced symptom, and the pulse gradually rises and becomes weak. The abdomen progressively distends. There is but slight muscular rigidity until peritonitis comes on. Palliative measures, such as enemata and massage, are less efficacious because the adhesions are firm and well organized.

The diagnosis soon becomes clear, and no time should be lost before operating. A median incision should be made below the navel and the obstruction relieved by adopting measures appropriate to the conditions found.

The chronic type of "late" obstruction has a more gradual and progressive course. Following the original appendicitis, whether operated upon or not, there may be a period of longer or shorter duration of perfect health, or the patient may complain of digestive disturbances, particularly from the side of the bowel activity. Constipation becomes more and more marked, relieved with greater and greater difficulty by cathartics and enemata. There may be slight attacks of intestinal colic with nausea. A diagnosis may be made at this stage, and that much to the patient's advantage. It would seem at this stage in some cases that abdominal massage and electricity

might avail to ward off complete obstruction. Careful watching of a patient with a history of appendicitis and with the above symptoms will enable the right diagnosis to be made. Oftener, however, that of intestinal indigestion is made, and the patient is plied with drugs, and put upon a rigid diet, with the result of causing loss of flesh and strength often of extreme degree. Chronic obstruction is caused by the gradual contraction of adhesions between two loops of bowel, or about a loop, or the gradual or periodic forcing of a coil beneath a band, etc., resulting in a progressive diminution in the caliber of the bowel. Persistence of these symptoms urgently requires operative interference. Sudden complete obstruction may come on at any time without obvious cause, or determined by an over-hearty meal or violent exercise. The symptoms then of acute complete obstruction are in full evidence, requiring active operative treatment.

Kocher, in the article cited later, lays down the following propositions: 1. The chief danger in each case of ileus rests upon the disturbances in circulation in the bowel-wall and its consequences, namely, venous hyperemia leading to hemorrhages and infarcts, edematous infiltration and the collecting of decomposing fluids in the intestine, injury and exfoliation of the epithelium and the consequent permeability of the bowel-wall for the passage of ferments, toxic substances, and bacteria.

2. This permeability leads, on the one hand, to general intoxication and infection, and, on the other, to local inflammation of the bowel-walls, necrosis of the same with ulcerations, perforation, and peritonitis.

3. The circulatory disturbances in the intestinal walls are caused by pressure from without upon circumscribed portions of the wall, and also by pressure upon the mesenteric vessels, due to strangulation by bands, internal hernias, volvuli, invaginations, etc.

4. Not less dangerous circulatory disturbances are caused by pressure from within, resulting from the stagnation of the intestinal contents, increased transudation and secretion above the obstruction, and the consequent overstretching of the bowel-wall.

5. In every case of ileus the immediate removal of the circulatory disturbances of the bowel-wall is indicated. This is accomplished, not only by removal of the extra-intestinal pressure, but also by doing away with the intra-intestinal stretching —the first can only be accomplished by means of a laparotomy,[1] the second without such a procedure, as by the formation of an artificial anus.

6. The slow development and chronic course of an ileus in no way restricts the absolute validity of the aforesaid indication, since the severest forms of ileus begin slowly, and the chronic forms may suddenly become acute.

7. The operative treatment of each case of ileus should be considered from the first moment. The non-operative treatment is suitable simply for those cases of obturation and dynamic ileus in which a strangulation ileus can surely be excluded.

8. The removal of the obstruction to the intestinal contents is desirable, but the removal of the circulatory disturbances in the bowel-wall is an absolute necessity of any operative procedure. Since the first indication in all forms of ileus is adequately met by a laparotomy, this is to be preferred in all forms in the beginning stages. In the late stages of obturation and paralytic ileus, the palliative operation (artificial anus) is indicated.

9. The previously bad prognosis of the operative treatment of ileus is exclusively caused by the too long delay in the carrying out of the operation, resulting in the gangrene of the wall, due to extra-intestinal pressure, or intra-intestinal stretching from increasing decomposition of the bowel-contents.

10. On account of the frequent uncertainty of the diagnosis in the early stages, a satisfactory recovery can only be expected by means of the radical operative treatment of every patient in whom there is a well-founded suspicion that a mechanical obstruction exists.

We may divide the cases with reference to the previous operation as follows:

1. Those in which the ileus occurs at the site of the previous operation.

2. Those in which the ileus occurs independent of the site of the previous operation, or afar from it, and only being indirectly due to it.

3. Ileus where no lesion can be found, *i.e.*, paralytic ileus.

Tavel, in a very elaborate and instructive series of articles (*Revue de Chirurgie*, October, November, December, 1903) on ileus in general, with particular reference to the diagnosis of the seat of the occlusion, gives the following symptoms of occlusion in the various regions of the intestinal canal:

1. *Pyloric Occlusion.*—The vomiting contains food with mucus sometimes mixed with blood, but without bile. The vomiting is no more in amount than is swallowed. There may be a few infrequent stools, and there is some passage of flatus. Pain is located in epigastrium and back. Resistance in pyloric region. Distention is local, limited to the outlines of the stomach, and does not fill up the whole epigastric region, as in duodenal occlusion.

2. *Duodenal Occlusion.*—Vomiting of food with or without bile and pancreatic juice. It is extremely abundant, and the patient rejects much more than is swallowed. From the stomach with the tube large amounts of bile and pancreatic juice can be obtained. The passage of feces and gas are infrequent, or completely absent. General meteorism of the epigastric region. Retraction of the subumbilical region.

3. *Ileo-jejunal Obstruction.*—Vomiting at first is mucus with food, mixed with bile, then consists of the contents of the upper part of the small intestine, becoming later fecaloid. Stools and gas

[1] By this Kocher evidently means the thorough searching for the cause itself of the obstruction.

almost totally absent. Distention is pronounced occupying the middle portion of the abdomen, the course of the colon being less distended or flat.

4. *Ileo-cæcal Occlusion.*—Vomiting more infrequent, and coming on later than in the previous variety and is fecal. Stools and flatus entirely absent. Distention the same as in the previous form and without pushing up of the liver or thoracic organs. Tenderness localized in the ileocecal region, and, in most of the cases, tenderness of the right pelvic wall by rectal or vaginal examination.

5. *Occlusion at the Hepatic Flexure.*—Vomiting appears late, and is fecal; can entirely fail. Stool and flatus absent. Distention pronounced, particularly of the ascending colon, with pressing upward of the liver and diaphragm. Tenderness marked in the region of the hepatic flexure. High enemata well retained. Tumor may be present.

6. *Occlusion at the Splenic Flexure.*—Vomiting much later, may be wanting. No passage of gas or feces. Distention very marked, particularly of the transverse and ascending colon, producing pressure upward of the diaphragm. Tenderness most marked in the left hypochondrium. High enemata not so well retained. Tumor may be present.

7. *Obstruction at the Sigmoid.*—Vomiting very late or absent. No stool or gas passed. Meteorism very pronounced. Whole colon distended. Pushing upward of the liver and heart, resulting at times in the disappearance of the dulness of these organs. No high enemata possible. Low ones fairly retained. If obstruction be situated in the iliac part of the sigmoid, abdominal palpation may elicit it, in the pelvic portion rectal or vaginal examination may be necessary to determine it.

8. In colon obstruction as distinguished from ileo-cecal, the large size of the tumor which may be present is to be noted, both palpable and percussible, and sometimes visible in its contour through the abdominal walls. In addition it is to be remarked that in the purely mechanical period there is usually no vomiting. This comes on when peritonitis sets in, *i.e.*, in the terminal stage. There are two methods which may help in the diagnosis of the seat of the occlusion when in the colon: 1. Insufflation of the colon with air producing tympanitic note and metallic tone in those points where it did not exist before. 2. Method of Treves of introducing water into the colon and progressively percussing the point of advancement of the fluid which will be arrested at the seat of obstruction.

(To be Continued.)

Urotropin in Scarlet Fever.—Urotropin is recommended highly as a preventive of nephritis in scarlet fever by D. BUTTERSACK (*Deutsch. Arch. f. klin. med.* Vol. 80, Nos. 3 and 4). If given in doses of 0.05 to 0.5 grams three times daily or twice as much of the citric acid compound, the drug is absolutely harmless, even where some renal irritation is already present. If not given throughout the entire course, it should be administered with the appearance of the first trace of albumin.

ASEPTIC CATHETERIZATION OF THE URINARY PASSAGES.[1]

BY M. KROTOSZYNER, M.D.,
AND
BY M. KROTOSZYNER, M.D.,
OF SAN FRANCISCO.

IN treating the subject of aseptic catheterization we must consider the sterilization of catheters, the preparation of the urinary canal, and the introduction of the instruments in an aseptic manner.

As metal catheters can easily be rendered aseptic by boiling, nothing further will be said of them. More difficult is the sterilization of flexible catheters, the majority of those in use being made either of soft or hard rubber, caoutchouc, or woven cotton and silk.

The literature of the last ten years is replete with publications of experimental work on the sterilization and preservation of these instruments. Aside from boiling, most of the methods recommended by various authors require expensive and complicated apparatus, which are not available to the average practitioner and out of the question for patient's use. We therefore conducted our experiments with the view of finding the simplest method of sterilization with the least impairment to the instrument. During our work we found that instruments infected with colon or mixed cultures from an infected bladder were more difficult to sterilize. It was also noticed that if the instruments were allowed to dry a day or two, a longer time was necessary for sterilization. We will here give briefly a few of our experiments with these instruments.

(A) SOFT RUBBER CATHETERS.

1. Catheter infected with colon; boiled three minutes; growth.

2. Catheter infected with colon; boiled five minutes; no growth.

3. Catheter passed into infected urethra and dried twenty-four hours; cut into three pieces: (*a*) Washed in soap and water; boiled three minutes; sparse growth. (*b*) Unwashed; boiled three minutes; growth. (*c*) Control; growth.

4. Retention catheter that had been in an infected bladder twelve hours; dried twenty-four hours; cut into four pieces: (*a*) Washed; boiled five minutes; no growth. (*b*) Unwashed; boiled five minutes; no growth. (*c*) Ends clamped so that boiling water could not enter the lumen; boiled five minutes; growth.

5. Catheter infected with colon; washed; exposed to formalin fumes thirty minutes; no growth.

6. Catheter infected with mixed culture; washed; exposed to formalin fumes thirty minutes; no growth.

7. Infected retention catheter; cut into two pieces: (*a*) washed; dried; exposed to formalin fumes thirty minutes; no growth. (*b*) Un-

1 Received for publication May 24, 1904.

washed; dried; formalin fumes thirty minutes; growth.

The apparatus used for sterilization with formalin consisted of a long glass jar, the open end of which was closed by a hollow metal stopper surrounded by rubber; the bottom consisted of a thin piece of copper. A formalin pastil was placed in the stopper and gentle heat applied (110 degrees to 115 degrees F.) for about fifteen minutes, or until the tablet was entirely disintegrated.

8. Infected retention-catheter; placed in Kutner's sterilizer three minutes; growth.

9. Catheter infected with colon; Kutner five minutes; growth.

10. Mixed infection; Kutner ten minutes; no growth.

The Kutner apparatus consists of a metal chamber surrounded by a water-jacket, in which steam is generated. The steam passes to the top of the apparatus, from which catheters are hung, then through the lumen of the catheters into the central chamber.

11. Catheter infected with mixed culture; washed and immersed in bichloride solution, 1:500, for fifteen minutes; growth.

12. Same as No. 11: (*a*) Thirty minutes; no growth. (*b*) Unwashed; thirty minutes; no growth.

13. Catheter infected with mixed culture; washed thoroughly in soap-spirits and running water; immersed in soap-spirits for fifteen minutes; growth.

(B) SILK-WOVEN AND HARD-RUBBER CATHETERS.

We repeated the same experiments as outlined under (A), and obtained practically the same results as regards sterilization.

(C) URETER-CATHETERS.

1. Catheter infected with colon; boiled three minutes in water; growth.

2. Infected with colon; boiled five minutes; growth.

3. Infected with colon; washed; formalin fumes fifteen minutes; growth.

4. Infected with mixed culture; soaked in five per cent. carbolic solution thirty minutes; growth.

5. Infected with colon; Kutner five minutes; growth.

6. Mixed infection; boiled in ammonium-sulphate solution four minutes; growth.

7. The same experiment as in No. 6; boiled five minutes; no growth.

We also experimented with various solutions of bichloride of mercury, carbolic acid and hydrochloric acid, etc., but found them unsatisfactory and unreliable for sterilization purposes.

Some of the methods, although safe as regards sterilization, cannot be employed because they proved to be too destructive to the instruments. Soft-rubber catheters stood boiling in plain water for five minutes for six successive days, and then became rather too soft for further use. Much better results in regard to their durability were obtained by boiling in a concentrated sodium-chloride solution. Silk- and cotton-woven catheters after one boiling in plain water showed blisters and small cracks in the varnish coating. They also became too soft for further use. While soft-rubber catheters did not do well in a saturated solution of ammonium-sulphate, we found that the cotton- and silk-woven, as well as the hard-rubber instruments, survived longer if boiled in that solution than in any other. They will stand, as we found, ten successive boilings of five minutes each, if put in the boiler thoroughly wrapped in gauze or a towel.

If several instruments have to be sterilized at the same time, they must be wrapped in a towel in such a manner that the surface of each instrument is entirely covered by part of the towel and does not come in contact with the neighboring catheters, or the sides of the boiler. In wrapping ureter-catheters into a towel, particular care must be taken that no part of the same ureter-catheter comes in contact with another part.

After boiling in the ammonium-sulphate the catheters must be thoroughly rinsed in sterile water to free them from the crystals of ammonium sulphate.

Steam sterilization, either by the autoclave or Kutner apparatus, is as injurious to flexible instruments as boiling. Although varnished instruments do not crack or blister so readily, after three of four steamings they generally become too soft for further use.

Sterilization by formalin is the least destructive, but as only the surface of the instrument is sterilized the utmost care must be taken that it is thoroughly washed and dried before being exposed to the fumes. Catheters of small caliber, as ureteral instruments, soon become clogged up by deposits within the lumen. The length of time needed for sterilization (at least half an hour), and the fact that the whole process of sterilization must be constantly watched, are serious obstacles to the use of formalin by the busy practitioner.

As the cystoscope is a means of ureter catheterization, we next experimented with its sterilization, which we found a more difficult task. The cystoscope cannot be boiled, for, as Casper points out, the prism lies in a metal casing, surrounded by cement. The connection between metal and glass does not permit of heating, as the expansibility of these materials is different. Besides the material used for cementing, the prism possesses a different expansibility, so that the prism will become loosened by frequent boiling and water may enter. The reflecting surfaces of the prism also suffer from heating, and the lenses become more or less opaque from moisture being deposited as soon as the instrument begins to cool off.

In a recent publication Casper describes the

following method for sterilizing cystoscopes: The non-removable parts of the instrument are rubbed for three minutes vigorously, especial attention being paid to the crevices and edges about the lamp and prism. The instrument is then snugly wrapped in gauze previously soaked in soap-spirits, in which it remains until ready for use. The removable metal parts are boiled five minutes. We experimented with this method in the following way:

1. Cystoscope infected with mixed culture and dried twenty-four hours; rubbed three minutes with separate pieces of cotton soaked in soap-spirits; washed in sterile water and plunged in bullion tube; growth.

Soap-spirits are made according to the following formula: Thirty parts alcohol, 17 parts H_2O, 7 parts KO, 6 parts olive oil (Gerson).

2. Same as in experiment number 1, except it was rubbed for five minutes; growth. Soap-spirits made according to formula of Hebra.

3. Same as in experiment number 1; growth. Soap-spirits made according to the formula of German pharmacopœa, which contains two parts of a high-grade oil-soap, two parts of rose-water and three parts of alcohol. It can easily be prepared by the physician himself and used in large quantities, as it is inexpensive.

4. After rubbing the instrument with soap-spirits for four minutes, it was wrapped in gauze soaked in soap-spirits, and allowed to remain twenty-four hours; growth.

5. Cystoscope infected with a mixed culture and dried twenty-four hours; washed in soap-spirits and warm water; rubbed with soap-spirits two minutes, then with alcohol for one minute; washed in sterile water and plunged in bullion; no growth.

6. Proceeded in the same way as in experiment 5, and then wrapped in gauze previously soaked in soap-spirits, in which it was allowed to remain four days; washed in sterile water; no growth.

The best results with the soap-spirits method were obtained if the gauze or towel used in wrapping the instrument was closely woven. If sterilized catheters, cystoscopes, etc., are snugly wrapped in closely woven towels, we are able to keep them in a sterile condition for quite a number of days (at least five days). The soap-spirits on drying forms an air-tight covering around the instrument by filling the meshes of the towel with soap. We lay stress on the fact that soap-spirits after the formula of the German pharmacopœa is to be used for soaking the gauze or towel, as soap-spirits prepared in other ways do not form the essential impermeable covering.

Cystoscopes can also be sterilized with formalin-gas without injury if the temperature in the chamber in which they are to be sterilized is not raised above 110 degrees or 115 degrees F. For this purpose we constructed an apparatus in the following way: A glass tube an inch and a half in diameter and about fourteen inches long is fitted with two stoppers. The one at the top consists of a cork with a perforation which allows the passage of the instrument as far as the ocular. The lower one consists of a hollow metal chamber surrounded by rubber, the bottom of which consists of a thin piece of copper. The formalin-powder or tablet is placed in the metal chamber and gentle heat applied. Here as in the sterilization of the catheters the instrument must be washed in soap and water and dried before exposing it to the formalin. Here are the results of some of our experiments with this apparatus.

7. Cystoscope infected with mixed culture and dried twenty-four hours; placed in formalin-chamber and gentle heat applied for fifteen minutes; washed in sterile water; plunged in bullion; growth.

8. Same as in experiment 7, but allowed to remain thirty minutes; growth.

9. Cystoscope infected with mixed culture and dried twenty-four hours; washed in soap-spirits and water and dried; placed in formalin-chamber and gentle heat applied for twenty minutes, and then kept in the apparatus ten more minutes; washed in sterile water; plunged in bullion; no growth.

Although the formalin method seems to possess a higher degree of safety as regards sterilization, still its application for general use will be marred for the same reasons stated above, requiring too much time and constant watching during the process of sterilization. We are therefore pleased to be able to recommend, from our work, the method as described in experiment 5 as the simplest and at the same time a safe procedure for sterilizing cystoscopes.

As to the question of keeping catheters, cystoscopes, etc., aseptic after sterilization, we found that the many devices, tubes, jars, designed for keeping catheters sterile, in the majority of which this is accomplished by means of a formalin pastil, unsafe. In order to keep instruments sterile for a reasonable length of time we recommend wrapping them tightly in a closely woven sterile towel, wet with soap-spirits made according to the German pharmacopœa.

As regards the introduction of instruments in an aseptic manner, it is a well-known fact that even the healthy urethra harbors various organisms, but it is doubtful if they are capable of infecting the mucous membrane of the bladder. Before introducing an instrument the meatus should be carefully sponged off with alcohol or a sublimate solution. Although it is impossible to free the urethra of micro-organisms, many authorities recommend, as a matter of precaution, the flushing of the urethra with sterile water or a solution of boric acid before instrumentation.

Another point is the choice of a lubricating agent. Oil can be sterilized by boiling, but this is a slow and dangerous procedure and the oil

soon becomes rancid. It cannot be used for lubricating cystoscopes as it blurs the optic; the same is true of vaseline. Both oil and vaseline form a tenacious coating on the instrument which cannot be easily removed in future sterilization, and, according to Casper, favors the lodging of infecting bacteria on the surface of the instrument. For this reason patients should be especially warned against the use of these lubricants.

Of late years we have used glycerin almost exclusively, the sterilization of which is unsatisfactory. Its great disadvantage, though, is that it is not a good lubricant and of no value where catheterization is difficult. More satisfactory is a combination of glycerin, tragacanth and water as originally recommended by Guyon and Kraus. Casper added cyanide of mercury to this combination in order to make it antiseptic. Culture tests made by him with this lubricant containing cyanide of mercury in a strength of 1:500 proved it to be antiseptic. The formula is tragacanth, 3.0; aq. destil., 100.0; glycerin purissim, 20.0; hyd. oxycyana, 0.246. Our experiments concur with those of Casper. It can be used for lubricating cystoscopes, as it dissolves readily in the bladder fluid, and therefore does not blur the optic. It is a good lubricant and is non-irritating. Being semi-solid, it can be kept in collapsible tubes, which facilitates its use. Care must be taken in its preparation, however, as some of the first tubes we obtained were very unsatisfactory.

In conclusion, we will briefly summarize those methods of sterilization which have proved to be safe and simple:

a. Soft-rubber catheters are rendered sterile by being boiled five minutes, preferably in sodium-chloride solution, care being taken that the solution fills the lumen of the catheter. As a matter of precaution the catheter should be washed with soap-spirits and running water after use.

b. Hard-rubber and silk- and cotton-woven catheters should be boiled five minutes in a saturated solution of sulphate of ammonia. Each instrument should be wrapped separately in gauze or a towel, or if several catheters are to be sterilized, in such a manner that their surfaces shall not come in contact with the sides of the vessel or other catheters.

c. Ureter-catheters can be folded and wrapped in a towel so that their surfaces are kept apart, and boiled for five minutes in a saturated solution of ammonium sulphate.

d. Cystoscopes should be sterilized by first washing them in soap-spirits and water, then vigorously rubbing them for two minutes with two different pieces of gauze or cotton, wet with soap-spirits, and then with alcohol for one minute. The channel for the ureter-catheter can be cleansed out by means of a brush, such as those used for cleansing pipes, first brushing with soap-spirits, then with alcohol.

e. Instruments can be kept aseptic if they are snugly wrapped in a piece of gauze or towel wet with soap-spirits.

VALUABLE SUGGESTIONS FROM THE INSPECTION OF URINE.[1]

BY IRA S. WILE, M.D.,
OF NEW YORK.

In the ordinary routine examination of the urine there are several preliminary factors meriting consideration. First the sample to be examined should be liberal and not a scant dram or so. Then it is essential that the specimen inspected should not represent any particular renal effort; nor should it serve as an index of vesical health for any definite period of the day. The sample studied should come from the mixed total urine for twenty-four hours. This is most important in order to draw accurate conclusions from chemical analyses, for twenty-four hour quantities serve as bases of urinary calculations. The specimens should be examined as soon as possible. To avoid change from fermentation or bacterial activity, it is advisable to place about one dram of chloroform or toluol in the container.

To regard a sample of urine wholly isolated from the individual voiding it is an error. The quantity for a child ten years old is not equal to that passed by a man of thirty years. The reddish albuminous urine of a menstruating woman gives no cause for alarm. The profuse watery urine of low specific gravity, passed by a festive alcoholic might agitate one to the extent of thinking of diabetes insipidus.

It is well to have in mind the approximate nature and amount of solid and fluid ingesta, medicines; likewise the age, sex and degree of bodily activity. The general condition of skin and lungs is often very suggestive in consideration of the amount of urine excreted, particularly during extremes of seasons. Climatic influences are manifest in inverse ratio between the excretory action of the kidneys and the lungs and skin.

What can be learned from mere inspection of urine? The eye can grasp in a moment such

1 Received for publication May 25, 1904.

details as quantity, clearness, color, foam, sediment. Odor is frequently very suggestive. Reaction is often indicative. Considering these factors as individual premises, it is our desire to revert to the conclusions they suggest. Here it should be stated that *mere inspection does not obviate the necessity of careful chemical and microscopical examination.* Inspection does, however, suggest to the busy practitioner features calling for verification: and frequently saves a valuable minute or so for other work.

Normal amounts of urine, 900 c.c. to 1,200 c.c. (females), 1,200 c.c. to 1,500 c.c. (males) offer nothing definite to the mind, though rather giving presumption of renal sufficiency and of disease, if any, being cystic. Increased quantity immediately places in the foreground two conditions with three others in the background. Very large amounts, 7,500 c.c. to 10,000 c.c., almost invariably are due to diabetes insipidus, while 2,500 c.c. to 5,000 c.c. point more toward diabetes mellitus. The rare condition of amyloid kidneys is suggested, although it seldom yields more than 3,500 c.c. Contracted kidney usually offers 2,000 c.c. to 3,000 c.c. Frequently a slight increase, as 1,500 c.c. to 2,000 c.c., is the mark of a worried chlorotic woman or a student around the nerve-racking examination time. Decrease in excretion is the general rule of all fevers, with the most marked example in tuberculosis meningitis. Ascitic conditions, particularly cirrhosis of the liver, as would be expected, yield scanty urine. The condition, par excellence, pictured by diminished renal excretion to the point of anuria is acute nephritis. Marked decrease in quantity always demands most careful investigation. Congested kidney seldom offers less than 500 c.c. to 800 c.c.

A study of the color of urine *requires* the total excretion for twenty-four hours. Color varies largely with the amount of water excreted, and this has its diurnal variations. The contrast between the clear, sparkling, colorless urine of diabetes insipidus and the dark-hued, scanty urine of acute nephritis emphasizes this relation. Tea, coffee, hard work, mental fatigue, serve to vary the amount of fluid excreted and influence the color, as does, indeed, digestion itself, or potation. Variations in yellow color depend in part on urobilin. Brownish hues suggest increase of urea urates, uro-erythrin, as marked in the urines of fevers and puerperium. It must be remembered that urines darken on standing—this being especially noticeable in phthisis. The average, normal color is bright yellow or pale lemon.

Halliburton, by a table of doubtful general value, sought to classify urines by color with relation to cause. Medicaments and foods may yield characteristic alterations, as the deep yellow of rhubarb, golden yellow of santonin, orange of chrysophanic acid, blue of methylene blue, brownish black of tar, carbolic acid, etc.

The principal changes of yellow from saffron to dark olive green or mahogany brown are due to bile. Occasionally after standing for a short time exposed to the air a grass green color may appear, owing to oxidation and formation of biliverdin.

Bluish cast or dirty greenish color may be due to indican. Rarely a specimen may not show this color until oxidation has been aided by exposure to the air. Variations from a smoky hue in acid urines to deep red in alkaline suggest hematuria or hemoglobinuria, which should be investigated chemically and microscopically. A slight pinkish color points frequently to nephritis, especially if noted during the course of an infectious disease. Intermittent occurrence of reddish colors may result from malarial hematuria or rupture of varicose veins at the neck of the bladder. Inspection of hemorrhagic urine gives valuable information as to the probable source of the blood—as will be considered below.

Very rarely is the dark brown of melanemia encountered. Lipuria and chyluria present a creamy urine. Diabetes mellitus exhibits in most instances a pale greenish or light yellowish green.

Foam ordinarily forms and disappears rapidly. If it remains for some time it suggests albumin or sugar. If the foam is colored yellow bile is present, though rarely a strong urobilinuria may cause a similar appearance. If the foam is blue methylene blue or very strong indicanuria is the likely cause.

The common odor of urine, described as "not disagreeable" and aromatic, may be changed to the ammoniacal odor of decomposition, as in cystitis, with retention. Fecal odor may lead to the suspicion of a fistula high up along the genito-urinary tract. The sweetish odor of diabetic urine at times gives way to the danger-signal—sweet apple smell of acetone. Some foods give a characteristic odor, as asparagus. Medicines likewise leave olfactory traces, and all are not as pleasant or aromatic as the balsams or the violet scent of turpentine.

Clearness of urine, as a rule, exists for a very brief period after voiding. The nubecula of mucus, phosphates, urethral and vesical epithelia soon forms. This little cloud is said to be more marked in the urines of females because of the vaginal epithelium.

The sparkling clearness of diabetic urine is no less important than the slimy turbidity of cystitis. Turbidity may be due to urates or flocculent phosphates, in which case a simple chemical test of heat and nitric acid will clarify the urine. Pyuria gives a variable degree of turbidity. In mild cases pus appears more as a general opacity of the urine. The pus settles in inverse proportion to the amount of mucus contained in the specimen. Opacity in red and brownish urines suggests blood. If the blood is well mixed, the kidneys are the probable source. If large clots are present, the bladder is the most likely seat of trouble. If small wormlike blood casts are present the probable origin of the hemorrhage lies in the uretus or pelvis of kidneys.

Mucus present in unusual amounts causes a viscidity, especially noticeable on attempting to pour the urine. If mucous shreds, commas, etc.,

are present, the diagnosis of gonorrhea is all but made. The microscope readily determines with exactness the nature of the disease. The large, irregular, fibrinous shreds suggest superficial vesical erosions.

Portions of tumors may be present, but whether papilloma, myxoma, or more malignant growth can be told only by the microscope. Seminal fluid frequently appears as the source of turbidity and is taken for phosphates until a drop of acid fails to dissipate it and the lens tells the tale. Chyluria and lipuria give a creamy appearance and on standing the fatty molecules rise to the surface, forming a pellicle.

The red, sandy, gritty crystals of uric acid are commonly present in uricacidemia and are readily told at a glance. Oxaluria may be confusing until the lens reveals the highly refractile "letter envelope" crystals of calcium oxalate. Tomatoes, rhubarb, apples, oranges and many other fruits and vegetables may be the cause of needless alarm. Bacterial turbidity is diffuse, not very intense, of finely granular appearance. The microscope alone can determine it.

The general appearance of the urine often tells an approximate specific gravity. As a general rule, the darker the color, the higher the specific gravity, for amounts of urine under 1,500 c.c. In larger quantities of pale urines, if the foam disappear readily, the specific gravity is probably low; if the foam persist, specific gravity is very likely to be high.

The reaction may be judged to a degree from the color, clearness and odor. "Smoky" urine is acid. Bloody urine of a pinkish hue is alkaline. Marked turbidity with viscidity is indicative of alkaline, as is the ammoniacal odor of decomposition. Precipitation of phosphates with turbidity also bespeaks alkalinity. The presence of uric acid crystals in fresh urine makes acidity a certainty.

Thus without the use of heat, chemical, or instrument, the urine aids in determining its own pathology. The inspection is in no way determinative, but merely suggestive. Mere inspection does not do away with the necessity of careful chemical and microscopical analysis. It simply serves to direct the attention of the busy practitioner to prominent features which require further investigation. If inspection can save time without sacrificing carefulness, if it can suggest without confusing, it deserves some slight consideration from those who speak with scorn of the "sunlight test."

140 West One Hundred and Fourth Street.

Site for Orange Hospital.—A deal has just been closed by which the Rev. F. Victor Romanelli, rector of the Church of Our Lady of Mount Carmel, of Orange, N. J., has secured the handsome house and estate of the late Samuel F. Jayne for the site of the new Catholic Hospital at Orange. Father Romanelli bought property containing three large dwellings adjoining the Jayne estate last spring. Both will be utilized as the site for the hospital. The main entrance will be through Centre street.

QUANTITATIVE ALBUMIN DETERMINATIONS.[1]

BY KARL M. VOGEL, M.D.,
OF NEW YORK.

In spite of the fact that the importance of the subject has stimulated the investigators of several generations to endeavor to produce some easily applicable, rapid method for the quantitative determination of the albumin in the urine, their efforts have thus far been fruitless. The number of reliable qualitative tests, which can be quickly carried out, is quite large, but the only quantitative procedure, which is entitled to consideration where accuracy is required, is the tedious and complicated method of drying and weighing the precipitate obtained on coagulating the albumin by heat.

Of the methods applicable to routine clinical work, those of Esbach and Purdy have perhaps the greatest claim to convenience and ease of execution. The errors attending the use of the Esbach tube are too well known to require comment, and in addition a delay of twenty-four hours is necessitated before the result can be obtained. The centrifugalization method of Purdy is also open to criticism on the score of variations in the density of the deposit due to differences in the specific gravities of the urines tested, and owing to the technical difficulties of ensuring an absolutely uniform speed of the centrifuge at exactly the prescribed rate of 1,500 revolutions per minute during the required length of time.

The convenience of volumetric methods has naturally led to efforts to introduce them into this field also. Tanret,[1] Boedecker[2] and Venturoli[3] years ago devised analytical schemes of this sort, but they have been discarded as untrustworthy. Sahli[4] has lately proposed a volumetric method in which the albumin is precipitated by heat, filtered off, and redissolved in a known amount of alkali and its amount determined by titrating with an acid, using Congo red as indicator, but he himself expresses doubts as to the reliability of the figures obtained in all cases.

The simplest and most promising of the volumetric procedures is that published by Wassiliew in the *St. Petersburg med. Wochenschrift*, No. 37, 1896. The author's description of the method has been reproduced, but without comments as to its reliability, in various publications, and Ditman, about a year ago, called attention to the possible availability of the method. The present study was undertaken as a continuation of his determinations, in order to establish the accuracy of the results to be obtained by this plan.

The method consists in the precipitation of the albumin by a 25 per cent. solution of sulphosalicylic acid, using an aniline dye known as echtgelb as an indicator, and then multiplying by an empirical factor to obtain the amount of albumin. It was found possible to simplify somewhat the technic of the process without in any way in-

1 Received for publication May 18, 1904.

validating its principles. The sulphosalicylic acid solution, which, of course, should be as accurately standardized as possible, can quickly be prepared by making it of such a strength that it exactly neutralizes two c.c. of a $\frac{N}{1}$ KOH solution, using phenolphthalein as an indicator. When made in this way, Wassiliew's factor, which consists of five decimals, may be reduced to the fraction .01, and if ten c.c. of urine be taken for the test, the percentage of albumin is obtained directly by noting the number of c.c. of sulphosalicylic acid required to produce the end reaction, and then moving the decimal point one place to the left.

The end reaction is by no means an easy one to determine, especially if the quantity of the indicator, two gtts., recommended by Wassiliew, is employed. It was found that the use of ten to twelve drops produced a much sharper end reaction without any apparent decrease of sensitiveness, the reaction being, if anything, more delicate with the larger amount.

The most advantageous technic was found to be as follows: Several portions of ten c.c. each of the urine measured with a pipette were placed in flat evaporating dishes of about seven cm. diameter. If necessary the urine was acidified with acetic acid, a frankly acid fluid appearing to give the sharpest end reaction. The same number of drops of indicator was added to each portion and the reagent then very slowly run in from a burette with constant stirring, as the union of the acid and albumin appears to take place somewhat slowly. The first portion tested was taken as a control, and after the end reaction had been reached, as denoted by the production of a red color, which did not appear to be deepened by the addition of a further drop of the reagent, a slight excess was run in. The titration was then carried out on the other portions in dishes of the same nature and under the same conditions of acidity and quantity of indicator as the first, the end reaction being reached as soon as the same shade of color as the control was obtained. Carried out under these precautions titrations on several portions correspond very closely.

In order to control the results obtained a number of gravimetric determinations of each urine were made and accurate averages thus secured. Six specimens of urine were used and each was also tested volumetrically, after dilution to one-half and to one-quarter with normal urine, thus making eighteen different albumin contents. It was found that the volumetric method gave fairly accurate results for urines containing more than .15 to .2 per cent. of albumin (the highest strength of urines tested was .27 per cent.), but that below this limit the percentage of error was so inconstant and high as to deprive the method of all claims to accuracy.

An important source of error appears to be the fact that even in normal urines a certain amount of sulphosalicylic acid must be added before the end reaction is obtained and as this is not a constant quality it would seem to be an irremediable defect of the method. It may be remarked in passing that the control determinations on which Wassiliew based the procedure were made by precipitating the albumin of the urine with alcohol, a method that has been found very unreliable.

The following table showing some of the averages obtained will serve to indicate the general character of the results yielded by the method:

No. of Specimen.	Amt. of Albumin in 100 c.c. Gravimetric Method.	Concentration of Urine.	Amt. of Albumin in 100 c.c. Titration Method.
I.	.245	Undiluted	.245
		Dil. to ½	.164
		Dil. to ¼	.140
II.	.137	Undiluted	.133
		Dil. to ½	.121
		Dil. to ¼	.120
III.	.222	Undiluted	.224
		Dil. to ½	.130
		Dil. to ¼	.122

Since the above study was begun, two authors, Spaeth[5] and Gerard,[6] have mentioned the method in their volumes on urinalysis just published. Spaeth condemns it utterly, and Gerard ranks it with the roughly approximate methods.

MEDICAL PROGRESS.

MEDICINE.

Optic Neuritis in Paratyphoid.—Ever since the paratyphoid bacillus has been discovered, attempts have been made to distinguish clinically between paratyphoid and typhoid. The symptoms are, however, so much alike, that the differentiation has more scientific than practical importance, except that a more favorable prognosis can be given in paratyphoid. The development of an optic neuritis in a case of the latter disease in the practice of G. FLATAU (*Münch. med. Woch.*, July 12, 1904), prove that even the rarer symptoms of typhoid may occur here.

Vincent's Angina.—Two varieties of bacteria have been found by A. UFFENHEIMER (*Münch. med. Woch.*, July 5, 1904) in the secretion of Vincent's angina, fusiform bacilli and spirilla. The former are not motile and are decolorized by Gram if abundant alcohol is used, while the latter are very motile and absolutely Gram negative. Both are occasionally found in cases suffering from other affections. The disagreeable fetor characteristic of Vincent's angina is probably caused by the spirillum. All attempts to grow the latter on artificial media have failed, but the *Bacillus fusiformis* could be cultivated for four or five generations on sterilized saliva, though it was impossible to obtain a pure culture, owing to the fact that all solid media were unsuited. Attempts at inoculating animals were all negative and when a small amount of the secretion was rubbed into the tonsil of a normal individual, no inflammation occurred.

Congenital Hypertrophy and Dilatation of the Colon.—Hypertrophy and dilatation of the large intes-

tine (Hirschsprung's disease) in the majority of cases is a congenital disease and the patients rarely reach an advanced age, since gastro-intestinal disturbances develop only too readily during the first year of life, owing to excessive putrefaction in the stagnant feces. If the patients survive the first years, the intestinal musculature may accommodate itself to the wide lumen and there may be no further trouble except that intercurrent attacks may endanger life. The majority of patients are males who suffer from a most obstinate constipation and perhaps never have a movement without the use of an enema. Inflammatory processes in the intestines are common owing to the irritation of impacted feces and much blood and mucus may be voided. At the same time the tympanites may reach marked degrees and the patients may be a menace to themselves and their surroundings by the frequent discharge of extremely fetid gas. From time to time there may be attacks of obstruction with complete cessation of peristalsis. Objectively the enormously distended loops are clearly visible through the emaciated parietes and gurgling may be very audible. In children the growth of the rest of the body is retarded, and the thorax eventually becomes deformed. L. Kredel (*Zeitsch. f. klin. Med.*, Vol. 53) reports a few cases of his own, and dwells at length on one where laparotomy was performed for supposed obstruction., There was no impediment to the passage of feces but a loop of colon was firmly caught in the pelvis. The only interference consisted in freeing this loop, but the patient improved wonderfully and no longer suffered from attacks of obstruction. In most cases, however, an operation is not indicated, except to clear the diagnosis or to correct a kink, etc., which may be the cause of an obstruction. The daily use of very large enemas of water or oil is indicated in most instances. A colostomy may be in place when the attacks of obstruction frequently repeat themselves or where an ulcerative colitis has developed, but great care should be exercised, since there is a tendency for the sutures to tear out owing to the great weight of the colon.

Embolic Gangrene After Pneumonia.—One of the least common complications of pneumonia is embolism of the systemic vessels. The patient of L. Kredel (*Zeitsch. f. klin. Med.*, Vol. 53) suffered from a typically severe lobar pneumonia and was convalescing when two days after the crisis a sudden intense pain was felt in the leg and the limb soon became blue and cold. Two weeks later an amputation became necessary in the lower third of the thigh. Probably the embolus came from a thrombus which had formed in the left ventricle, since the patient had presented irregular heart action and a systolic murmur during the course of his pneumonia.

Essential Albuminuria.—C. Posner (*Zeitsch. f. klin. Med.*, Vol. 53) thinks it is a mistake to diagnose a nephritis in every case where traces of albumin are excreted. With delicate tests albumin may be detected in almost every urine, but larger quantities often occur in the so-called essential albuminuria and merely signify that the renal filter has become less dense without, however, altering the appearance or function to such an extent that a nephritis may be assumed. If the histories of such cases be studied in detail, an infectious disease will often be discovered as cause, but even after years the amount, appearance and specific gravity of the urine will remain normal and casts are uncommon or absent altogether. The treatment consists in proper diet and mode of living, since the kidneys undoubtedly form a *locus minoris resistentiæ*, and a nephritis may follow after the use of much alcohol, etc.

Changes in Corpuscles of the Blood in Puerperal Fever.—Examination of the blood in cases of puerperal sepsis has led Profs. Potocki and Lacasse (*Ann. de Gyn. et d'Obst.*, June, 1904) to the following conclusions as to its value for diagnosis and treatment; a certain amount of information can be elicited which will aid in the prognosis of a case; at least we can distinguish certain grave forms. Even if there be a high leucocyte count with a marked increase of the polynuclear forms, the prognosis remains favorable if the eosinophiles do not disappear. Where there is present a phlegmasia alba dolens, even in spite of the leucocytosis (30,000) or the polynuclear increase (90 to 95 per cent.) there may be a diminution of the eosinophiles. In the severe cases which recover, the eosinophiles increase as the polynuclears decrease in percentage. If the leucocytes go above 25,000 to 30,000 and the polynuclears are between 80 and 90 per cent. the prognosis should be guarded, especially if the increase is accompanied by the diminution in the eosinophiles.

Relation of Appendix to Pelvic Disease.—All operators are agreed that whenever the abdomen is opened for other abdominal or pelvic disease, the appendix should be examined and removed if diseased. The fact that a number of appendices thought to be normal at the time of operation proved subsequently to necessitate a second operation, led R. Peterson (*Am. Jour. Obstet.*, July, 1904) to study two hundred appendices, grossly and microscopically, removed in cases operated upon for distinct gynecological lesions. These were classified in six groups, as follows: Negative, 32.5 per cent.; chronic inflammation, 28.5 per cent.; doubtful significance, 20.5 per cent.; former inflammation, 14 per cent.; acute inflammation, 3 per cent.; peri-appendical inflammation, 1.5 per cent., this last class including two cases of tuberculosis and one of primary carcinoma of the appendix. The social condition of the patient had practically no bearing on the relation of the appendix to pelvic disease. In 8 per cent. of the cases fecal concretions were found macroscopically, their presence did not necessarily indicate that the appendix was diseased. In cases with chronic disease of the appendages 41.5 per cent. showed diseased appendices. Uterine fibromata were present in 26 of the 200 cases, in 50 per cent. the appendices were normal. In 24 cases of ovarian cystomata 70.9 per cent. of the accompanying appendices were diseased, a proportion larger than with fibroids. It was further concluded from the study of these cases that only about 50 per cent. of appendices removed during operations for pelvic lesions are normal; that the average length of the appendix is between 8 to 9 cm., the maximum length being found between the ages of twenty and thirty years; that menstrual pain may be due or enhanced by an inflamed appendix; that the shape of the appendix, the presence of adhesions, acute or chronic disease of the appendages cannot serve as indices of normality or disease of the appendix. Since it is impossible by gross appearance alone to determine which appendix may be diseased and since 50 per cent. of appendices removed in cases where the abdomen was opened for other purposes are diseased, the surgeon should, in the absence of contra-indications, remove the appendix in every such case.

Anchylostomiasis.—Baroni (*Gazz. degli osped.*, June 12, 1904) concludes that anchylostomiasis is a disease which if diagnosed early is neither dangerous nor hard to cure. If not recognized or properly treated it can be fatal to the patient and expose others to the infection. An enormous quantity of ova are passed by each patient, which rapidly develop into larvæ, which can penetrate into other human beings. This may take place by feces being passed into water, or earth that is being cultivated, and the hands of laborers become contaminated. Epidemics of anchylostomiasis are not unknown. When a man shows the typical anemia with other symptoms he

should be separated from other workmen and his feces burned. The chief symptom is a grave anemia, which does not readily yield to iron, suggesting pernicious anemia, latent malignant tumor, gastric atrophy or malarial cachexia. Microscopical examination of the feces will show the eggs, though this may have to be repeated several times. The intoxication of the organism is the cause of the various symptoms, shown especially by the toxicity of the urine; treatment consists in emptying the intestine, and preventing a rigorous diet. Thymol and castor oil are the best drugs. The patient should remain in bed.

Disinfection of the Biliary Passages.—Of the various disinfectants which pass over into the bile, F. KUHN (*Zeitsch. f. klin. Med.*, Vol. 53) found that thymol and menthol possesses the strongest antiseptic properties. With ordinary medicinal doses the amount secreted would not, however, be sufficient, so that the next drug on the list, sodium salicylate, is recommended. In a strength of 0.1 per cent., the growth of germs is retarded, while 0.6 per cent. will completely sterilize the bile. Drugs which act in higher concentration are naphthol, aspirin and citarin, but ichthyol and saccharin are almost valueless.

Hyperacidity in Gastric Cancer.—It is well known that anacidity is the rule in cancer of the stomach, except where the tumor has developed from an ulcer, or marked nervous symptoms are present. V. ZIEGLER (*Zeitsch. f. klin. Med.*, Vol. 53) has, however, seen several cases where the previous history did not point to ulcer or nervousness and where distinct symptoms of hyperacidity were present. He divides the disease into three stages: (1) Stage of uncomplicated hyperchlorhydria in patients of advanced age, formerly well. Half to two hours after meals these patients complain of pressure in the epigastrium and heart-burn. Though the appetite is good, coffee, wine and tobacco no longer agree and constipation is obstinate. The test meal will show a total acidity of 90 to 120, with 58 to 80 free hydrochloric acid, but without lactic acid or characteristic bacilli. The physician believes he is dealing with a case of ulcer or simple hyperchlorhydria, but the usual treatment causes no improvement. (2) The amount of acid may be normal, increased or diminished. Mucus is increased and motility impaired. The general condition is no longer good and the patients complain of anorexia, loss of weight and pain, no matter what is ingested. The tongue is coated and traces of lactic acid with Boas-Oppler bacilli may be found in the stomach. In the third stage finally the patients present the usual picture of cancer. It is clear that a diagnosis may be impossible during the first and second stages, but attention should be directed to the following facts: (1) Silver nitrate, bismuth, alkalies and atropine only cause temporary improvement. (2) A remarkable dislike toward meat is often present. (3) The advanced age will speak against uncomplicated hyperchlorhydria, and there may be some anemia. (4) The development of a gastritis with impaired motility is very suspicious.

Diagnosis of Anemia.—E. BIENACK (*Zeitsch. f. klin. Med.*, Vol. 53) is strongly opposed to the common practice of calling every patient with pale mucous membranes anemic. Anemia is a dilution of the entire blood, and can only be diagnosed by an exact analysis of the amount of hemaglobin and the number of red cells present. If the blood of many pale patients be examined, normal figures will often be obtained for the dry residue, and iron, instead of improving, will make the condition worse. The patients really belong to the large class of functional neuroses and their pallor is due to spasmodic contraction or congenital stenosis of the peripheral vessels. The characteristic yellow color is not present and heart murmurs do not occur. The author believes that fully 60 to 65 per cent. of all so-called anemics belong to this class.

Systemic Infection with the Colon Bacillus.—In cases with typhoidal symptom-complex but no clear history of typhoid, it should not be forgotten that the colon bacillus may be the cause. The patient of W. BAUERMEISTER (*Zeitsch. f. klin. Med.*, Vol. 53) presented the following symptoms: Continuous fever, severe headache, chills, vomiting, pains in back and abdomen, slight bronchitis. Characteristic symptoms of typhoid, such as roseola, swelling of the spleen, diazo and hypoleucocytosis were not, however, present. The diagnosis was established beyond doubt when colon bacilli were grown from the blood and urine. The patient improved but amputation of the testicle became necessary later. From the testicular pus, a germ was isolated which resembled the typhoid in many respects, yet the author believes it was merely a colon bacillus with diminished virulence.

Cause of the Pulsus Paradoxus.—Pulsus paradoxus is a name applied by Kussmaul to a pulse which becomes smaller during inspiration and regains its normal volume with expiration. Since the symptom has been most frequently observed in chronic mediastinitis it has generally been assumed that adhesions connecting the aorta with the neighboring structures have been responsible. E. REICHMANN (*Zeitsch. f. klin. Med.*, Vol. 53), however, offers the following explanation: During normal respiration the difference between expiratory and inspiratory intrathoracic pressure is so slight as to be without influence upon the blood within the great vessels. If dyspnea, however, is present, the difference is much greater and more blood will be received into the aorta during the marked negative pressure incident to inspiration, so that the peripheral pressure falls considerably. This will naturally be more marked where heart-action is feeble or bands press on the vessels.

Early Diagnosis of Gastric Cancer.—Many bacteria have been found at various times in the stomach contents of patients suffering from gastric cancer, but only the long or Boas-Oppler bacillus seems to have diagnostic importance. In a case which had been examined repeatedly by S. HEICHELHEIM (*Zeitsch. f. klin. Med.*, Vol. 53), these bacilli were never found, until the expression contained a blood-clot which turned out to be almost a pure culture. A diagnosis of cancer was then made, and confirmed at operation. Other cases were then examined, and small, brown coagula with bacilli found in almost every instance, except where the tumor had not yet ulcerated. In simple gastritis with diminished or absent hydrochloric acid, the coagula are very rare, and if they do occur, will never contain such masses of bacteria. Indeed, their presence seems to be one of the earliest signs of cancer. Even in tumors secondary to ulcer, and with considerable free hydrochloric acid, such clots are frequently found.

Hyperacidity and Its Treatment.—If stomach analyses are made systematically in all disturbances of the digestive tract, even when the symptoms are not primarily gastric, one will be astonished to find how common hyperacidity is. In many cases the patients themselves are totally unaware of this condition and merely complain of symptoms referable to neurasthenia. In a second class, the main complaint is constipation, and drugs with change in diet, directed against this will often cure the stomach as well. The third type has distinct gastric disorders and the nutrition is often below par. In these cases C. v. NOORDEN (*Zeitsch. f. klin. Med.*, Vol. 53) has seen the best results from enforced feeding. Even where there is a distinct anatomical lesion, as in acid catarrh and gastric ulcer, it is desirable to give large amounts of food after the first eight or ten days of moderation.

SATURDAY, AUGUST 27, 1904.

HEAT EXHAUSTION AND SUMMER DIARRHEA.

It is well known that summer diarrhea in children occurs much more frequently toward the end of the summer than during its earlier weeks. The reason for this is acknowledged to be that the hot weather reduces the resistive vitality of the child. At first the infant is able to stand a certain amount of irritation of the gastro-intestinal tract without severe reaction. After it has been weakened, however, by exposure to heat and milder attacks of digestive disturbance during the early part of the summer, severe and even fatal diarrhea may result after only slight irritation.

Notwithstanding the recognition of these facts, and the indications to which they so clearly point, they are not always heeded. The most important element in the care of a child during the hot weather must be to keep it cool. For this purpose it is necessary that it should be very lightly clad, should not be allowed to sleep on soft, yielding beds or pillows, and should be frequently bathed in cool water. We have come to realize now that thermic fever may exist in slight degree without necessarily going to the extent of actual unconsciousness or other severe forms of so-called sunstroke. We know, too, that if patients are kept cool the danger of such thermic fever becoming serious is very much lessened.

Dr. Illoway has recently insisted, in his little volume on the "Summer Diarrheas of Infants," that thermic fever is not infrequently the basis of the pathological condition on which severe summer diarrheas develop. If by various artificial means children can be kept cool there is much less likelihood of these dangerous complications. There is still a prejudice in the minds of most people with regard to the frequent use of cool water for children's baths, and the medical profession could confer no greater boon on the suffering little ones than to emphasize the necessity for frequent bathing, not only after the infant has begun to show signs of irritability from the severe hot weather, but as a prophylactic measure, while it is still in good health.

Besides this there is need for emphasizing that important element of baby's care, the significance of which is only just beginning to be generally realized, that for comfort's sake the infant must be handled just as little as possible.

As the summer advances and resistive vitality and irritability increases, handling is more and more objectionable. Adults find contact with one another during hot weather extremely disagreeable. Infants, unable to secure any change for themselves, are sure to suffer even more. The bacteria productive of gastro-intestinal disturbance are only one element in the production of disease, the other is the lack of individual resistance, and there are those who would insist that this latter is quite as important, and that, indeed, on it depends the virulence of the disease.

RECENT STUDIES ON RADIUM.

As might very well be anticipated from the exaggeration of the first accounts with regard to the employment of radium in medicine and surgery, there has been a decided reaction, and some assertions have found their way not only into newspapers, but even into the medical press, that radium can be of no possible service in therapeutics.

It will be of interest then for our readers to note that at a meeting of the New York Academy of Medicine, held May 19, an account of which will be found in the society proceedings of this week's Medical News, observers who have been faithfully working with the metal, but not announcing their results before they knew what their results really meant, have some encouraging

things to say with regard to the therapeutic possibilities of a new and marvelous substance of which so much was expected, and not without good reason.

At that meeting Dr. Piffard called attention to the fact that the radiations from radium occupy an intermediate position between those which are used for therapeutic purposes in the Finsen light and the X-rays. His expression that the radiations of radium are really a transcendentalized pocket edition of the X-rays expresses this thought very succinctly. The radium rays are not simple, but consist of alpha, beta and gamma rays, which have been observed from other sources as well as radium, but seldom in such readily available quantity as from this new element. The alpha rays are probably positive electrons, the beta rays are negative electrons. Both of these are corpuscular in character and have a definite size and weight. The so-called alpha rays are material particles, probably of about twice the size of an atom of hydrogen. The beta rays are probably of about one-thousandth the size of an atom of hydrogen. As the atom of hydrogen has been up to the present time considered so small as to be the standard of weight in atomic weights in chemistry, it can readily be understood how minute this new particle of matter is thought to be. The gamma rays from radium are true etheric waves, probably not corpuscular in character and possess great penetrative power. The alpha and beta rays are very much hindered in their action by the material in which the radium is kept. Glass, for instance, lessens their activity to a very great extent. Dr. Piffard has found that aluminum makes a much better substance as a retainer for radium than glass. In most cases the external pressure is produced by the emanations of radium, which are different from the radiations from radium, and which are found to be mainly composed of helium. These force their way through defects, air bubbles and the like that may exist in the glass phials in which radium is kept. Even when aluminum is used, Dr. Piffard has found that the emanations find their way apparently through the pores of this metal, and their disappearance always leads to a lessening of the radio-activity of the radium. As a consequence he has found it necessary to enclose the aluminum tubes in which radium is kept within tubes of some other metal, using silver for the purpose because of its density.

Dr. Abbe called attention to certain recent observations with regard to the biological effects of radium. If seeds are exposed to the action of the metal for several days they are very much retarded in their growth. Those seeds are most retarded which have been longest exposed. On the other hand, in insect life a very curious result has been noticed. If the larvæ of insects are exposed to radium, those that survive the exposure fail to go through the ordinary transformations and to exercise their reproductive capacity. Meal worms, for instance, exposed to radium do not become pupæ and then beetles which lay eggs, out of which further meal worms develop, but continue a prolonged existence as meal worms. These meal worms live on for several generations after their contemporaries metamorphosed, have given life to new generations which in turn have gone through their transformations in a natural way. The exposed meal worms may live the length of several generations in the worm stage without any tendency to be transformed.

The application of such an inhibitory property for the rapidly multiplying cells of cancer at once suggests itself. Where the radium can be so applied as to act directly upon the cells of malignant growths either sarcoma or carcinoma, it has the happy effect that might be anticipated. There is every reason to continue the experimental use of the metal in surgery, especially as lupus, warts and other benignant skin tumors are favorably affected by it.

A TEXAN WELLSPRING OF PLEASURE.

That certain people are possessed of a certain peculiar power, and are endowed by nature with some inherent ability to perform minor miracles, has long been a popular belief. Thus, as the law of compensation always enlarges the supply to meet the demand, we have become surrounded with an increasing class of astrologists who can read their victims better than they can the stars, and of fortune-tellers who will prognosticate anything for the moderate sum of one dollar.

These people all, however, belong to the genus "fake"; they live in cities and are surrounded by the paraphernalia of their trade, and if anyone is fool enough to part with his money to them it can generally be regarded as a divine interposition on the part of Providence to prevent it luring him into more serious trouble. As a class they all bear a striking resemblance to each other. The men are, as a rule, thin and hectic, a cross between the Edwin Booth Hamlet type and that of

the melancholy Jaques, while the women, on the contrary, are possessed of that exuberant glandular development which is characteristic of advanced maternity, with blondined hair, the roots of which seldom justify the ends.

Of the making of these imposters, like that of books, there is no end, but that, as Kipling says, is another story. But every now and then some apparently well-authenticated case comes up of the alleged power of some particular individual to do a peculiar thing that is "beyond the power and against the ken" of the ordinary mortal. These manifestations usually occur in what might be called the middle register, both in regard to the social position of the performers and their age. Another singular fact seems to be that these mediums have no previous knowledge of the power that lies in them until it suddenly breaks out in a volcano-like eruption, and that the evidence of it seldom becomes apparent until long after the consciousness of its possession would have been of the greatest financial advantage to them. This, however, in most cases, is soon remedied, and the nebulous current derived from God is speedily short-circuited to serve the practical purposes of Mammon.

Now, if "Mammon was the last ejected spirit that fell from Heaven," as we are taught, there is every reason to believe that she alighted with the dull thud of gold in Texas. It also seems that Henry Zachary, a plowboy of fifteen years, can be metaphorically cited as a corespondent in her fall, and that he was mashed by her. At all events, a few short weeks ago he was eating bread and cheese, when he could get it, with a strong and healthy appetite. He was also supporting himself and his blue jean overalls by the single suspender of a strict attention to drawing his furrow as straight as the Texan law allowed; while his financial standing in the community was synonymous with that of the church mouse.

Now it is all changed, for the wealth of Ormus and the Ind is his, and his plowshare has been rebeaten into the sword that has pried open the oyster of success. He has a two-bladed "Barlow knife" and gum galore to chew, while his dependent father loafs in a Tuxedo coat about the farm and smokes "seegars." All this is due, it seems, to a magic power that the boy's hands possess, by which, according to the published report, he can "locate minerals, water or oil at a great depth, with a certainty never before known." It appears that while he was holding the plow in one of his father's fields he was seized with a peculiar and well-defined tingling in his fingers whenever he passed over a certain part of the lot. This sensation returned, too, with accumulative effect, on every succeeding arrival at this particular spot, until he was forced to cry out for his father's help.

Now, Farmer Zachary is not a typical visionary man. Strong he is, and planted firmly on feet that can trudge uncomplainingly over more rough ground than two strong oxen can plow from morn 'til night. So he ridiculed the boy, and told him "not to take his hands from off the plow," and quoted Scripture to him. But all without avail. Finally, as the father was unable to do two things at once, he stopped plowing and began to think. Wearying with the unaccustomed task, he at length arrived at the conclusion, reached by the most acute of all French minds, that it takes longer to think about a thing than it does to do it, and he promptly acted.

Well diggers were set at once to work and found a goodly supply of excellent water, though at a considerable depth below the surface. This miracle was repeated on a neighboring farm, and then the lad's fame spread, like a wave of the incoming sea, completely over Caldwell County, submerging the local divinators and floating their forked twigs and rods out into the dim ocean of obscurity.

And now no man can dig a well without his aid, or sink a shaft until his tingling fingers have pointed out the spot; nor, if report be true, will these peculiar hands, that have become cramped around the handle of the plow, unbend into any practical usefulness until the itching in the open palm is soothed away with Mammon gold.

ECHOES AND NEWS.

NEW YORK.

Entertainment for German Scientists.—The "Union of Old German Students in America" will entertain the German Scientists who attend the St. Louis Congress of Art and Sciences at a "Commers" in Arion Hall, October 8. Most of the eminent guests are medical men.

Dr. Bellamy Injured.—Dr. J. R. Bellamy was injured in a polo game at Van Courtland Park August 17. It was feared that he had sustained a fracture of the skull, but it was said at the Fordham Hospital later that Dr. Bellamy was gradually regaining consciousness and that his chances of ultimate recovery had very much improved.

Gouverneur Physician Exonerated.—An examination into the death of Henry M. Miller, a Bellevue Hospital orderly, at the Madison street police station on Sunday morning, has resulted in the exoneration by the Bellevue Hospital authorities of Dr. A. W. Taves, of the Gouverneur Hospital staff, who was called to attend

Miller in Seward Park the previous evening. Dr. Taves offered to take him to the hospital, but he refused to go in the ambulance, and as he was not under arrest Dr. Taves could not forcibly take him. Later Miller was arrested and taken to the police station, where he died. The physician's action in the case has been approved by the hospital authorities, including the superintendent of Gouverneur Hospital.

St. Elizabeth's Hospital in Litigation.—The Supreme Court has been asked to direct the Windsor Trust Company to pay over $70,000 which the Pennsylvania and Long Island Railroad companies paid as the fixed value on St. Elizabeth's Hospital, at 223 and 225 West Thirty-first street, a part of the site of the new Pennsylvania terminal station. There is some discussion concerning the disposition of the funds arising from the fact that the old hospital was conducted by a lay order, while the new one is to be conducted by the church.

Health Department Examinations.—An examination of applicants for the position of assistant physician in the hospitals for contagious diseases connected with the Department of Health will be held at the Willard Parker Hospital, at the foot of East Sixteenth street, on September 1 and 2, 1904, at 2 P.M. Applicants should have had a general hospital training, or practical experience in the care of infectious diseases. The positions are salaried. Examinations will be both written and practical, and will include general medicine, surgery, pediatrics, bacteriology, pathology and infectious and contagious diseases.

An Effort to Decrease Infant Mortality.—The Department of Health has issued explicit directions for the care of infants during the summer. The damp weather of the last two months has caused an extraordinarily high infant mortality, the average since July 2 having been 377 a week, against an average last year of little more than 200. Much is done by charitable citizens and institutions by providing excursions to the country for the sick children. It is impossible to afford opportunity for more than a trifling part of the infants of the poor to get fresh air. It is practicable, however, to see that every family is properly instructed in the rudiments of nursery hygiene and sanitation, and organized effort in this direction has led the Health Department to formulate the following instructions: *First*—Nurse the baby, and nurse it regularly, about every three hours. If you cannot nurse the baby consult your own physician or send to the Department of Health for a physician. *Second*—Do not give the baby condensed milk. *Third*—Never use the loose milk sold in grocery stores as food for the baby. *Fourth*—Never give the baby raw milk in warm weather. *Fifth*—Use only bottled pure fresh milk, properly prepared and sterilized, and feed the baby at regular intervals, about every two and a half or three hours. *Sixth*—In the morning prepare and sterilize enough milk to last the baby during the day and until the next morning. Cover each bottle and place on ice after sterilization. *Seventh*—See that the nursing bottles and nipples and all dishes used to hold the milk are kept absolutely clean. Wash these utensils in hot soap suds and then rinse in scalding water each time before using. *Eighth*—The water that is used to dilute the milk must be boiled. *Ninth*—Send to the Department of Health for a circular telling just how the milk should be prepared and how the baby should be fed and cared for, or notify the Department of Health that you want a trained nurse to show you how to prepare the food. *Tenth*—Send at once to the Department of Health or for your own physician if the baby becomes ill. Stop giving milk during the illness of the child, and give the milk only when the physician directs it.

PHILADELPHIA.

Jefferson Hospital.—Work on the new building is progressing, most of the first set of posts of the superstructure being in place. A small portion of the east side of the old building has been taken down to allow building of a new chimney.

St. Luke's Hospital.—Contract has been let for alterations on the new building at Broad and Wingohocking streets. The work will be completed by the end of November, when the hospital will be moved from its present location. The new plot is 225 by 400 feet, which gives ample room for additional buildings.

Certificates for Pharmacists.—At the examination held by the State at Williamsport on July 19, 87 of the 155 applicants were successful in obtaining certificates. Among these were 56 of the 101 who took the examination for registered pharmacist and 31 of the 56 examined for qualified assistant's certificate.

Ask Power to Cancel Licenses.—The Pennsylvania State Board of Medical Examiners is to ask the legislature to grant the power of recalling and cancelling any license issued by them. This is for the purpose of dealing with any person who from lack of education other than medical, or because of his moral character being of such degree, is not qualified to act as a physician. Such men may now practise until caught at some criminal operation. Hereafter certificates are not to be given by the board to illiterate candidates, even though they possess the requisite technical knowledge. It is believed that the power to revoke licenses will prove the best method of dealing with malpractitioners.

Examination of Athletes at Pennsylvania.—Dr. R. T. McKenzie, the new physical director of the University of Pennsylvania, will allow no student to participate in any line of athletics unless examination shows the man to be fit to endure the strain. The evils which the medical profession point out in the overexertion and physical injuries of college sports are brought about by the lack of just such examinations as will, in the future, be compulsory at this college.

CHICAGO.

Lessened Mortality Among Young Children.—The City Health Department has the following to say regarding the low mortality among children this season: "One of the most remarkable features of the present season, as to the public health, is the unprecedentedly low mortality from contagious diseases of childhood, and as a consequence a very low general death rate for the city. Only one death each from diphtheria and measles, three from scarlet fever, and four from whooping-cough were reported during the week. Since the first of the year have been 21 deaths from diphtheria; during the corresponding period of 1903 there were 328 diphtheria deaths, a decrease this year of more than one-third. Deaths from scarlet fever show a decrease of 52.2 per cent.—241 last year, 115 this year. In the whooping-cough mortality the decrease is 80 per cent.—241 deaths in 1903, 48 in 1904. Against the 23 deaths from measles since January 1, 1904, there were 258 in the corresponding period of last year, a decrease of 91 per cent. The gross mortality of the four principal contagious diseases of childhood thus far in 1904 is not much more than one-third (37.3 per cent.) that of the corresponding period of 1903."

Prevalence of Smallpox in Zion City.—Sixteen cases of this disease are reported from Zion City, and the adjoining towns are taking precautions to prevent its spread.

Mortality for Week.—Acute intestinal diseases head the list of deaths with 111; violence caused 62 deaths;

consumption, 56; heart disease, 41; Bright's disease, 29; cancer, 22; and pneumonia, 20. The total deaths were 496, equivalent to an annual death rate of 13.41 per one thousand.

GENERAL

Gift to St. John's Hospital at Yonkers.—The late Cornelia A. De Wint has bequeathed to St. John's Riverside Hospital at Yonkers, $10,000.

Tuberculosis Congress.—The American International Congress on Tuberculosis will be held October 3, 4 and 5, 1904, under the auspices of the Universal Exposition, St. Louis, 1904, the American Congress on Tuberculosis and the Medicolegal Society of New York.

Supposed Dead Doctor Returns.—Dr. R. G. Lightle, who was supposed to have been burned in his barn at Searcy, Ark., May 22, and on whose death insurance companies paid $19,000 on policies, has returned. He says he went away suddenly because he had a corpse in his barn for dissection, and when the building burned he feared he might be arrested for grave robbery.

Vaccination in Hydrophobia.—Consul General Guenther, at Frankfort, Germany, has supplied to the State Department official statistics concerning the efficacy of vaccination as a preventive of hydrophobia. The substance of these is that only 1½ per cent. of persons bitten by mad animals and vaccinated have died. The figures also show that Russia is the breeding place of hydrophobia.

Snake Venom and Cold-blooded Animals.—The action of snake venom on cold-blooded animals has been tested by Dr. Noguchi in a long series of experiments (Carnegie Institute of Washington, Publication No. 12). Three venoms were employed, viz., those of the cobra, water moccasin and rattlesnake. Snakes and frogs succumb easily to cobra venom, but are relatively insusceptible to the other venoms; turtles are more susceptible to all venoms than the foregoing, and fish are still more so. The grasshopper and some crabs are almost insusceptible, while the lobster is only moderately resistant. Excepting the earthworm, all the worms showed a low degree of susceptibility. The venoms have little effect on the *Echinodermata;* sea urchins succumbed, however, but starfish and sea cucumbers were not perceptibly affected.

Nerve Energy and Electricity.—Recent investigations by Dr. Jacques Loeb and others, according to the *Sat. Evening Post*, seem to point to the conclusion that the nerve centers of the human body are in a true sense storage batteries charged with electrical energy. It is not unreasonable to imagine that what we call fatigue may be due to the temporary exhaustion of the battery-power. The batteries contained in the "wings" of the fish known as the "torpedo ray," which is able to inflict a shock that will stun a man or a horse, are regarded by anatomists as modified muscles. They are composed of an arrangement of cells, corresponding to small Leyden jars, in which electricity is stored through the medium of the nervous system—a fact proved by the circumstance that, when the connecting nerves are severed, the organs lose their power to give a shock. It is much the same way with the so-called "electric eel," and with a species of catfish which is likewise a dealer in small thunderbolts. Observation of the phenomena described makes obvious the close relation between electricity and nerve energy. When the human body is at rest the storage batteries, which are called the nerve centers, are slowly charged. During the day the supply of energy is gradually dissipated, and nature demands another period of repose in order to refill the battery cells. Such, though the theory is as yet more or less speculative, is the belief toward which science at present is leaning.

Asepsis and Antisepsis.—It has been known for some time that a reaction was in progress from the extremes to which the German school has carried asepsis in surgery, says the New York *Times*. The movement started by Lister was in itself a reaction from the slovenly practices which obtained before his time and had something of the character of a reform. Professor Dr. O. Rosenbach, of Berlin, in his "Arzt contra Bakteriologie," finds the courage to enter the lists with the following challenge: "The time is not far off when antiseptics will, in most cases, be used only for disinfecting the external skin and the instruments. Water and soap will be reinstated in their place of honor as cleansing materials. The quintessence of antisepsis, as explained long since by many successful operators whose work is done without the aid of bactericides, which, in truth, had better be called tissue destroyers, or protoplasm poisons, will be reduced to an endeavor to avoid the introduction of additional virulent agents into the human organism by our operative measures which must in part destroy the protective barrier of the organism owing to the necessity of entering the interior of the body; therefore, to operate with clean hands, clean skin, and clean instruments, as well as, above all, to handle or squeeze tissues as little as possible in order not to reduce their defensive apparatus by local necrosis, and thus to assist in facilitating the process of regeneration. That all this may be accomplished by the simplest means of relief, provided practice and dexterity are in evidence, reducing the insults to a minimum, is illustrated by the history of ovariotomy. An operator who works gently and deftly, and does not imagine that under cover of strict antisepsis any and every abuse of tissue is licensed, will always command brilliant results. The dogma of the efficacy of purely external disinfection being such absolute protection as to render superfluous any regard for the patient or the healing powers of nature, has been provocative of more mischief than the adherents of absolute protection by means of toxic antiseptics will ever care to acknowledge." In commentary the *Times* says that perhaps the pendulum-swing in his case only illustrates the law that action and reaction are equal, and it may very well be that the truth lies somewhere midway between the views he combats and those he announces.

Control of Opium in Formosa.—In the report of Mr. Consul Playfair on the trade of North Formosa particulars are given of the manner in which the opium trade is regulated. The authorities are doing their best to put down the opium habit; no one but the government is allowed to deal with opium in any way, save those who are licensed. Only those proved to be addicted to opium are given permission to buy and smoke it. Exceptionally heavy penalties are inflicted on those detected in importing, selling or smoking the drug without permission. The revised regulations for the application of the opium law show that the government makes three qualities. Agents and dealers in opium have to be non-smokers and persons of good character. They are licensed, as are the smokers, and the latter must always produce their licenses when purchasing opium, of which only a certain quantity can be bought. The price is fixed by the government, and the selling agent who supplies the retailer is only allowed a profit of 1½ per cent. He pays three yen a year for his license, and has to report monthly the quantity and value of the opium he has sold since the last report. The retailer also has to pay three yen per annum for his license, and has to keep a careful account of his transactions and report to the police. The attempt to control the opium habit caused at the outset many disturbances, and the authorities found great difficulty in ascertaining the number of smokers, as people refused to give information; it was not until late in 1900

that it was believed that all the opium smokers in Formosa were registered. Since that date it is reckoned that the number of smokers has decreased by about 1,000 a month. There are three grades of opium made at the government factory, all of which those who can afford to buy a first class ticket (red) at 3 yen per month may purchase and use. The second class smoker pays 1 yen 50 sen per month for a green ticket, entitling him to buy the second and third grades of opium, while the third class smoker pays 20 sen monthly for a yellow ticket, conferring the right to indulge in the commonest quality only. The use of opium in Formosa is steadily declining, the result not only of law but also of public opinion.

Japanese Field Surgery.—Dr. Louis L. Seaman, of New York, writes that the Japanese are giving proof of the benefits to be derived from the non-interference with wounds on the field, where they content themselves with the application of first-aid bandages and antiseptics, leaving the more serious work to be done in the hospitals at home. This course is followed except where there is danger of the wounded man bleeding to death or where his condition is very precarious. The result of this practice has been that many men suffering from bullet wounds at the front are nearly well when they reach Japan. In one hospital ship returning to Japan from the front there were 2,200 wounded men, and there was not a single death on board during the trip. There have not been more than three deaths among the wounded who have been returned to Japan after having received first-aid treatment only. If the Japanese soldier is not killed outright, Major Seaman says, the chances are that he will recover. His temperate habits and his plain and healthful diet of fish and rice, varied occasionally with meat, contribute much to his recovery. Russian wounded captured by the Japanese have been treated in a similar manner, and the recoveries among these men are scarcely less in proportion than among the Japanese. A new complication has been discovered in the wounds sustained in this war due to the extraordinary high speed of small-calibre bullets, which produce aneurisms by their speed. Dr. Seaman saw twenty-seven operations performed for the relief of this condition.

OBITUARY.

DR. D. M. BARNETT died August 21, at his home, in Claremont, Texas, aged ninety-five years.

DR. GEORGE T. HESTON, a descendant of Llewellyn, King of Wales, died at his home at Newtown on August 19, aged seventy-eight years. He studied at Haverford College and the University of Pennsylvania, and later made a trip around the world as surgeon on the bark Adelaide.

DR. J. FREDERICK NOTT, of New York City, died in the Maine General Hospital, at Portland, Me., August 19. Dr. Nott, who had boarded an express at Kennebunk, bound for Bar Harbor, was taken ill a short while before the train was due in Portland, and when that city was reached his condition was so serious that it was decided to remove him to a hospital.

Physical Deterioration Among the English.—The English Inter-Departmental Committee on Physical Deterioration has issued its report in London. It deals at length with conditions of employment, urbanization of people, depletion of rural districts, question of food, etc. It may be necessary, the committee says, in order to complete the work of clearing overcrowded slums, for the State, acting in conjunction with the local authority, to take charge of the lives of those who, from whatever cause, are incapable of independent existence up to the standard of decency which it imposes.

SPECIAL ARTICLES.

BYWAYS OF MEDICAL LITERATURE.—XXII.

CHEMISTRY AND MEDICINE.

A VERY interesting article on the relation of modern chemistry to modern medicine, an address delivered before the Sigma Xi Society of the University of Kansas, by Professor J. H. Long, furnishes an excellent idea of how far chemistry can be helpful in practising theory in modern medicine. Especially with regard to the much-disputed question in recent years of the action of ferments, Professor Long's opinion should be known by all those whose duties as teachers lead them often to talk of ferments and fermentations. Very seldom has a difficult question been put so clearly, so simply, and at the same time so thoroughly up to date.

"It was certainly an auspicious day for chemistry, and medicine also, when Pasteur developed his biological theory of alcoholic fermentation. Not long after came the work of Kühne, Brücke and others on the enzymes, already referred to, and finally Buchner, to clearly demonstrate the long-suspected enzymic character of the yeast ferment. Practically all recent work in this direction has gone to show that so-called organized fermentations are all dependent in turn on enzymic ferments contained within the cells. This distinction may probably be made: In the yeast fermentations, for example, the sugar to be converted is drawn into the cell, and the products, alcohol and carbon dioxide, formed by the zymase, are in turn excreted. In diastasic and similar fermentations, on the other hand, certain cells produce an active ferment which is discharged to do its work outside the generating cell. The difference is thus seen to depend on the place where the reaction occurs, which is not a very important point. The ferments are essentially complex chemical substances, able to bring about various reactions, nearly all of which are of exothermal character. Of the nature of many of these reactions we have pretty accurate knowledge, although of the exact mode of action of the enzyme itself our knowledge is scanty. For the present purpose, however, it is sufficient to recognize that these reactions are chemical and we are in a position to trace their bearing on medical problems.

"The simplest problems of enzyme action we have in the work of some of the so-called digestive ferments. In the changes wrought in starch by the saliva and by one of the pancreatic ferments the chemical action is one of hydrolysis and very similar to that occurring commonly in the vegetable world. In the germinating seeds, when starch becomes sugar to feed the developing plantlet, water is added through the aid of diastasic ferments, and later, in the ripening of many fruits the same kind of reaction takes place. These effects, however, are not peculiar to the enzymes; experiment shows that the same starchy substances acted upon by weak acids pass through the same series of changes occurring in the body, and even prolonged heating with water has the same general effect. The hydrolytic and purely chemical nature of carbohydrate digestion becomes at once apparent. What happens in the digestion of fats is equally simple. Here, too, hydrolysis plays the most important part and the work of the lipase enzymes can be duplicated in the vegetable kingdom and also in the laboratory by the aid of the simplest of inorganic reagents. A far more difficult problem for a long time was to account in any way for the changes taking place in the digestion of proteins. The presence of a proteolytic enzyme in the gastric juice, was recognized definitely by Brucke over forty years ago, and about the same time a substance called trypsin was found in the

extract of the pancreas. These substances acting on proteins under certain conditions convert them into a series of intermediate and end products about which an enormous literature has been developed. In the course of the long discussion it was discovered that many of the products which are formed by the enzymes may be obtained by the action of weak acids or alkalies, or water even, at an elevated temperature, on the original proteins, and finally, it was shown that an increase of weight follows in these cases as in the case of the addition of water to starch. All this evidently places the phenomena of protein digestion in the group of hydrolytic reactions, along with the much simpler starch and fat reactions. The digestion processes are, therefore, chemical, and the only thing about them which remains mysterious is the fact that from one set of body cells a ferment working in acid medium is produced, while from a second set of cells a somewhat similar ferment working in an alkaline liquid is secured."

MAREY'S LIFE WORK.

The death of the experimental physiologist Marey is another reminder of the progress made in our senses as well as in medicine during the last half century. His great work was the application of graphic methods to the study of animal movements. It was back in the sixties that he began inventing the registering apparatus for heartbeats, and the sphygmograph is now a classic instrument of observation. But for the general public his success in photographing successive animal movements have had the most striking results.

Let any one compare the prancing, symmetrically balanced steeds of Horace Vernet's battle pictures with the representations of horses in rapid motion made by artists since Meissonnier and he will see how great an education the human eye has received in a few years. Meissonnier painted before Marey's investigations, and all the critics fell foul of his horses. Marey proved that Meissonnier simply saw movements accurately and that the galloping steed of previous painters was usually as much a dream of the painter as are the crude drawings of children. He pointed out that the ancient Greeks had also seen the horse accurately in their sculptures. No one doubts it now, and we have all learned to look a little sharper and with more instant analysis.

It is true that the eye is not a photographic lens, but rather transmits to our consciousness something like a composite of the rapidly succeeding movements. But we have learned to look intelligently at nature in motion, just as impressionism has led us to attend more closely to the shades of color of nature in repose. Marey's work on the flight of birds in like manner showed that the Japanese artists had caught the truth of motion in the matter, and now our own designers have learned the trick. An accepted demonstration in mechanics was upset by one of his disciples who followed his methods and photographed sixty-five successive movements made by a cat in falling from a height, turning on herself in the air, and landing safely on her feet. Here, too, the popular notion was true and science had to revise its calculations, which was brilliantly done by a young French mathematician in his thesis for his doctor's degree.

Up to his death Marey was engaged in this visual interpretation of mechanical science, which has been so fruitful in his hands. I cannot appreciate here the immense sum of work accomplished in other lines by this typical Frenchman of science of devouring activity. His last writing was to urge the importance in traction vehicles of elasticity as an economizer of work. He has long been attached to the Agricultural Experiment School (physiological station), kept up by the French Government, and he had a laboratory at the College de France. With a moderate but sure maintenance and facilities for his special experiments and for the publication of results, his career has been one of ideal success, for the professor was devoted to his calling. Honors came to him thickly, and he had long been a member of the Academy of Medicine and of the Academy of Sciences.

YE OLDEN TIME DOCTOR.

The *Atlantic Monthly* some months ago published some leaves from the notebook of an old-time practitioner of medicine that are of great interest, and that bring home very well the differences of practice then and now. The experiences are told in straightforward fashion, with all the simple details that show their truth to nature and make them worthy to be preserved in the notebooks of those who are interested in the history of medicine. Of course the prominent feature of practice was as it always has been and doubtless will be an assumption of knowledge as to the exact diagnosis of disease which favored the persuasion of a hopeful therapeutics. Always general terms have been employed to cover a multitude of diseases and at the same time the ignorance of the physician. An impartial survey of the state of our own diagnosis and therapeutics will temper our ridicule of his. Perhaps it may even serve to inject a wholesome element of the doubt that happily leads to investigation and, consequently, to progress:

"I saw a vast deal of practice, I assure you. Besides children's diseases, we had quinsy sore throats and congestion of the lungs, as well as pneumonia, and what I wrongly pronounced 'Chilson fever.' But generally we diagnosed the case as liver trouble, and treated accordingly. Sometimes we gave calomel in pills, but we thought we got better effects from powders; the pills were so large and were so unevenly covered with a bitter powder,—and, though I became expert in rolling them, still they would bulge and stick and gag the people, who either could not swallow them, or else had later accidents,—that, as I say, we thought best of powders. And when I say powders, have you in mind a dainty paper with a pinch of salt, as it were, within its ingenious folds? Go to! Do you think we were mere homeopathists? We gave it in a teaspoon filled from a frequently replenished bottle carried in the doctor's capacious side pocket!

"This was the favorite medicine with patient and physician. No more grateful compliment came to the professional ear than the familiar 'I tell you, doctor, that last dose took hold right smart,' received with the complacent 'Well, I reckoned it would.' When salivation ensued, and the poor wretch had not a yellow tooth that did not rattle as he praised our skill, and the rebellious stomach refused to assimilate juicy spare ribs and the hot Sally Lunn, we gave him bumpers of bicarbonate of soda mixed with Brown's Essence of Jamaica ginger. He was taught that the disease was working out of the system, and that the ghastly symptoms were the inevitable sequelæ of a mysterious dispensation, which they probably were!

"We gave bushels of quinine, in tea to women, whisky, more plentiful than tea, to the men. I have spoken of calomel as the trump card which we played in the game with death, but I am not sure that we did not oftener take the trick with the lancet. We were hampered by no modern septicemic fears. The little instrument, arranged with an ingenious spring to prevent its opening, was carried in the vest pocket along with a plug of tobacco, a toothpick, and odds and ends of every sort. I doubt if there was a day we did not find use for it. We bled for headaches and fevers; we bled for congestion

of the lungs; we bled the negroes for their ills, generally designated by the generic term 'misery.'"

The touch that shows how high was the estimation in which the kindhearted old-time doctors were deservedly held is not lacking. One is tempted to wonder if with all our advance in medicine we do our patients as much good as our comparatively ignorant medical ancestors. They inspired the confidence they felt themselves in their remedies and that is half the battle of therapeutics. When they could accomplish nothing their never-failing sympathy almost made up for their lack of effciency and won them tender places in the regards of their patient, such as are not won by their more skilful brothers of succeeding generations. The whirligig of time brings in its revenges, but there are compensations always.

"It was etiquette with us that when a doctor fell ill the oldest physician in the town should have charge of the case, while all the others came in in consultation. There were thirteen in this town of less than three thousand inhabitants, and they all went through that sick room, following Dr. Ireland, the dean, and looked wise. Then the doctor sent for me. He said there was no luck in odd numbers, and, more than that, I understood his constitution! I spent many hours with him, and we talked of everything except medicine.

"But he did not get well.

"'I think some men have to get sick to get rested,' he said one day, when my face must have showed what I feared,—for, indeed, I feared greatly, most of all because he took no medicine. So at last I spoke. 'Doctor,' I said, 'would calomel or jalap do? Or, I know how to bleed.'

"And the old fun flushed his face as he said, 'Doctor, it wouldn't be etiquette without Dr. Ireland. Besides, dear little boy, burnt brandy wouldn't help me now.' The next day he died.

"The town was as full of spring carts and buggies and saddle horses the day he was buried as if it had been the day of the county fair. The negroes, breaking the bonds of their Protestantism, prayed aloud in the streets for his soul,—and the clergyman said: 'This man sought neither riches nor honor, but gave himself for others. Fifty years from now his name may be a faint memory, but I think he was one of those whom God depends upon to keep the world good, and to bless little children by his gentleness and purity and cheerfulness.' And all the people said, 'Amen.'"

THE CIRCULATION OF THE BLOOD.

THERE is nothing more interesting, as there is certainly nothing more promising, than the many references in present-day medical literature to discoveries in medicine made long before the date usually assigned for such discoveries. There is at the present time a very sympathetic rereading and rewriting of passages of medical history in such a way as to give due credit to many patient faithful investigators of the olden time who found in their observations much more of truth than is usually supposed to have been possible before distinctly modern times.

The Harveian Oration in England was founded with a distinct idea of having an address delivered each year before the Royal College of Physicians of London on some subject connected with the circulation of the blood. It is especially encouraging then for those who are interested in truth for its own sake in medicine to find that the last deliverer of the Harveian oration, Dr. Richard Caton, the emeritus Professor of Physiology at the University of Liverpool, in fulfilling his task in this matter touches upon observations nearly related to the discovery of the circulation of the blood in Egypt some 5,000 years ago.

Dr. Caton dwells particularly upon the benefits conferred upon medicine by a learned physician who lived during the third dynasty about 3,500 B.C. He attained such eminence that in the course of subsequent ages he was deified and became for later generations the special god of medicine under the name of I-em-hotep, which means "He who cometh in peace." Later he became one of the great god triad of Memphis, and is described as "the good physician of gods and men, a kind and merciful god assuaging the sufferings of those in pain, healing the diseases of men, giving peaceful sleep to the restless and suffering; he is called the creative god, who giveth life to all men, who comes unto them who call upon him in any place and who gives sons to the childless."

Dr. Caton considers that the very early Egyptians practically discovered all that the Greeks subsequently knew about the functions of the heart and of the blood, and that it is indeed to their discoveries and not to actual observation that the Greeks owe what has come to be attributed to them by later generations. He said:

"It is of some interest to note that these priests of I-em-hotep, themselves learned men, not only saw and prescribed daily for vast numbers of sick persons, but also performed innumerable necropsies. They removed the heart, large blood vessels, viscera and brain from the bodies of diseased persons, also from the bodies of sacred animals, prior to embalment; the heart was placed in a separate jar by itself and the remainder of the viscera in a larger vessel; thus these men had an opportunity of learning something of anatomy; they may have gained some insight into the intricate problem of the action of the heart, the movement of the blood, and the changes of heart and vessels produced by disease; no nation of antiquity had such opportunities. Did they discover anything? I think I can demonstrate to you they did obtain a partial knowledge of the circulation; they did not solve the problem, but they approached it as nearly as did the Greeks, and probably from them the Greeks obtained such knowledge as they possessed in early times."

Of course all question of the circulation in early times were found to contain not blood but air, and that they were supposed therefore to be channels through which was obscured by the fact that after death the arteries the air of the lungs found its way to various parts of the body. Dr. Caton quotes, for instance, some comments from the early papyri which go to show how much more can be found by a sympathetic reader in these old medical documents than our distant predecessors in medicine were ever supposed to know. As a matter of fact there are some things in which there has been no advance even down to our own day. He said to his audience in the Harveian oration:

"Let me read you one or two extracts from the work of the Pharaoh Usaphais, quoted in Eber's papyrus: 'Man hath twelve vessels proceeding from his heart which extend to his body and limbs, two vessels go to the contents of his chest, two vessels go to each leg, two to each arm, two vessels go to the back of the head, two to the front of the head, two branches go to the eyes, two to the nose, two vessels go to the right ear, the breath of life goes through them, two go to the left ear and through them passes the breath of death; they all proceed from the heart.' The concluding sentence is the earliest example I know of the ancient superstition that the left side of the body is sinister and evil. This is very early anatomy, professing to be at least 6,000 years old; we must not expect it to be quite accurate. Turning to a comparatively recent period the only copy existing of Eber's papyrus (found in a tomb at Thebes) was written in or before

the sixteenth century B.C. No doubt most, if not all, its contents are much older than that date. The passage which I am about to read commences: 'From the secret book of the physician a description of the action of the heart and of the heart itself. From the heart arise the vessels which go to the whole body; if the physician lays his finger on the head, on the neck, on the hand, on the epigastrium, on the arm or the leg, everywhere the motion of the heart touches him, coursing through the vessels to all the members' (the reference is clearly to the pulse); thus the heart is known as the center of all the vessels. Four vessels go to the nasal chambers, of which two convey mucus and two convey blood. There are four vessels within the temples or skull. From these the eyes obtain their blood. The four vessels divide inside the head and spread toward the inner part.'

"The Berlin papyrus speaks of the division into thirty-two vessels within the skull and implies that air traverses at any rate some of them. Returning to Eber's papyrus, 'When the breath enters the nostrils it penetrates to the heart and to the internal organs and supplies the whole body abundantly.' This idea that certain of the vessels convey air you will observe is identical with the Greek conception and probably was its source: 'Three vessels traverse the arms and extend to the fingers, three vessels also pass down the leg and are distributed to the sole of the foot, a vessel goes to each testis and one to each kidney. Four vessels enter the liver, conveying fluid and air; these may be the seat of various diseases as they are mixed with the blood; four vessels convey fluid and air to the intestine and spleen; two go to the bladder and from them the renal secretion is produced. Four vessels convey fluid and air to the lower abdomen, going to the right and left sides; from them is formed the alvine excretion.' The vessels here described are clearly the iliac arteries and veins. 'When the heart is diseased its work is imperfectly formed; the vessels proceeding from the heart become inactive, so that you cannot feel them' (no doubt this is a reference to changes in the pulse), 'they become full of air and water. When the heart is dilated the vessels from it contain effete matter. If a suppurative or putrefactive disease occur in the body' (abscess, I imagine, for which various sites are suggested) 'then the heart causes it' (apparently the purulent material) 'to traverse the vessels, fever or inflammation of various kinds occurs in the body, the heart is in a morbid state while the fever continues. In heart disease there is either disturbance of the action of the heart or the heart is congested or overfilled with blood, the heart is moved downward, comes nearer the precordia, and suffers weakness and nausea. When the disease affects the base or lower mass of the heart there is shortness of breath, the heart is displaced on account of the volume of blood from the abdomen' (probably the old idea of the rush of blood entering the heart from the liver). 'There may be fever or inflammation of the heart.' Now here comes a passage of some therapeutic interest. 'The heart during such disease must be made to rest to some extent if it be possible.' Here we have wise advice from the ancient Egyptians, advice the importance of which we have scarcely as yet recognized and which we may to-day follow with advantage. 'If the heart is atrophied (or wastes itself) there will be an accumulation of blood within it. When the disease of the substance of the heart is accompanied by dropsy there is a lessening' (in strength probably) 'in the ventricle or cavity. When the weakness of the heart is due to old age there is dropsy. When there is raising or increase of the heart it presses toward the left side, it is increased by its own fat and is displaced; there may be much fat contained within its covering or pericardium. If in a suppurative disease the heart is pushed forward it floats or sinks in the fluid and is displaced.' Here we surely have a reference to pericardical effusion. 'If the heart trembles or palpitates, has little power, and sinks downward, the disease is advancing. When there is much beating at the precordia, with a feeling of weight, when the mouth is hot and languid, and the heart is exhausted the disease is a fever or inflammation.' In another place (folio 102) the heart is spoken of as being full of blood, which comes or flows from it again. In folio 39, after a description of symptoms, follows a statement to the effect that the heart is distended, the sick man is short of breath, because the blood has stagnated and does not circulate. This is an interesting expression, but judging from other parts of the papyrus the word tanslated circulate can only have a vague meaning, implying movement to and fro, just like the expression περιόδος αἱμάτος in the Hippocratic writings, which seems to imply the circuit of the blood, but in reality has only a similar indefinite meaning. It is evident that the Egyptians knew that blood flowed from the heart, but, like the Greeks, they never seem to have realized that the heart is a pump, nor did they recognize valves."

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, held Thursday, May 19, 1904.

The President, Andrew H. Smith, M.D., in the Chair.

Fever Curves of Scarlatina and Measles.—Dr. A. A. Berg said that the fever curves of measles and scarlet fever are quite as typical as those of typhoid fever or smallpox. This is not usually stated in the text-books, but will be found absolutely true in typical cases. There is the stage of accession, that of fastigium and that of defervescence. Each of these may occupy from hours to days. The beginning of fever is sometimes spoken of as prodromal, but it does not precede the eruption which is already present on the mucous membranes. In the eruptive stage it must not be forgotten that the fever is first enanthematous and then exanthematous. In measles, during the enanthema, the pyrexia is marked and it may last for from two to five days. Then there is a sharp decline. On the first day of the exanthemata in measles the pyrexia is one degree higher than before. On the next day it is still a degree higher. Usually on the third day it is at its highest and only then is there a drop. The drop is always noticed to occur in the morning.

Scarlet Fever Curve.—The febrile curve of scarlet fever is much simpler, yet it is characteristic. The enanthematic eruption is followed by the exanthem in six hours to, at most, a day. The top notch of the fever is reached on the first day of the enanthem. This never occurs in measles. The exanthem is followed by a drop of two or more degrees. When the eruption is extensive, the temperature may rise half a degree more, but the defervescence is usually maintained. Scarlet fever declines by lysis and never resolves by crisis. The access is sudden and the fastigium lasts from five to six days with staircase descent. Scarlet fever is said to occur occasionally without fever, but this Dr. Berg has never seen. The curves of these diseases are always typical, and whenever there is a departure from the normal some reason for the exception can be found. When the decline of the fever in measles does not take place by crisis, some complication may be looked for, usually pneumonia or nephritis. An irregular curve should always give rise to suspicion. When regular

descent by lysis is interrupted in scarlet fever, a complication should be feared. The temperature curve may readily be made a test for the value of antitoxin. The normal curve in diphtheria is easy to recognize, and after the administration of antitoxin there is a critical defervescence which takes place in twelve hours. This is quite an exceptional incident in the fever curve and indicates the thorough effect of the serum. No such critical defervescence occurs after the administration of Marmorek's or Moses's serum for septic infection, showing that the action is evidently of quite different nature. High fever in children's diseases may require treatment. Cold or cool baths or cold sponging or cold packs are the most recommended. Antipyretic drugs are scarcely justified in children. The temperature cannot be reduced as in typhoid fever or pneumonia, for the reaction of the cutaneous circulation is different. The patient's nervous system can be calmed best, however, by hydrotherapy. Owing to the irritation of the skin, the capillaries are much more dilated and will not contract under the influence of cold. Hence, there is neither the primary contraction nor the secondary dilatation seen in other fevers. It must not be forgotten that the blood is loaded with toxins and that the eruption is eliminative in character. Accordingly the encouragement of gentle perspiration in mild cases by a warm bath with a dry pack will often be found very efficient.

Technic of Bathing.—The bath should be given at about 80° F., not lower, and raised to 90° while the patient is kept in it for ten minutes longer. This makes a warm bath, though the temperature of the water is lower than that of the skin. Then the patient should be wrapped lightly in a sheet or light blanket and put to bed. In order to have the warm water mixed properly with the cooler water in the tub, when the temperature of the bath is being raised, the warm water should be poured to the bottom. No rubbing should be practised, as in typhoid fever, as this will only cause premature desquamation and practically produce small ulcers. A large, soft sponge may be used, or the skin may be patted with a soft towel.

Curve of Enanthemata.—Dr. Koplik said, in discussing the paper, that as yet the curve of the enanthematic stage of the fevers is not known. The prodromal curve of the infectious fevers is not characteristic, and from a look at the temperature sheet a little patient might easily be suffering from tonsillitis, when one of the infections would be suspected. That there is a critical drop of the temperature in measles has long been known and classical cases are reported in the text-books. Uncomplicated cases, however, do not always conform to the type, and notwithstanding febrile anomalies there may be no complications in the ears, throat, lungs nor gastro-intestinal tract. Suspicion should always point however, to one of these. Dr. Koplik has never seen a case of measles without a temperature, though in one typical case the temperature was only 99.8° F. by the rectum. When scarlet fever drops very slowly, an enlargement of the lymphatic glands may be found, usually due to an acute dermatitis. There are so many variations from the type, however, in different ways that the temperature curve cannot be considered of great value in diagnosis or prognosis. The therapy must not be based on the thermometer, for cases are very individual and some children suffer severely at a temperature at which others are quite comfortable.

Postcritical Temperature.—Dr. Lambert said that in measles there is usually a distinct crisis, but it is not uncommon to have a rise in temperature afterward up to 100° or 101° F. without complications. He has seen two cases of typical measles run their course without temperature. They had complete desquamation in six weeks and yet at no time was the temperature curve above 99° F. Scarlet fever may come down very slowly and yet no complication be present. The febrile course may be two weeks without complication. In such cases desquamation goes on during the febrile period and the patients need to stay no longer in the hospital. The temperature of scarlet fever is as irregular as typhoid, and Delafield said that nothing was too irregular for typhoid.

Opposite Febrile Charts.—Dr. Northrop said that the fever of measles and scarlet fever is quite typical, so that it is possible to write the chart beforehand in most cases. If the charts are on lantern slides it would be only necessary to start them from different ends in order to have the different courses of the two diseases. A combination of the two makes a typical smallpox chart. Antipyretic treatment should be directed not by the thermometer, but by the patient. There need be no fear that the eruption will strike in because of the application of water. It is important in these cases to keep the feet warm and the head cold.

Dr. Berg, in closing the discussion, said that some children play lustily with a temperature of 103° F. The measles fever chart has its exceptions, of course, but it is as typical as typhoid. The point in bathing that Dr. Berg would insist on is that the temperature should be raised at the end, beginning at lukewarm. This is better than the bath at 70°, or even 60° for reducing temperature.

Definite Information as to Radium.—Dr. H. G. Piffard said that there has been a vast amount of misinformation furnished by the daily and weekly press with regard to radium, and that as a consequence there is a reaction against the possibility of its being of any benefit in medicine, which is not justified by the true results of investigation. The radium rays consist of three kinds, the alpha, beta and gamma rays. The alpha rays exist in the largest proportion, but have very little penetrating power. The beta rays are smaller in amount, but have more penetrating power and, in Dr. Piffard's opinion, are like the cathode rays of Crookes's tubes. The gamma rays seem to be the same as the X- or Roentgen rays, existing in small amounts but have great penetrating power. The alpha rays are affected by a magnet, being attracted to it. The beta rays are also affected, but are deflected; the gamma rays are non-deviable by magnetic attraction. Besides the radiations there is an emanation from radium. The emanation from radium consists of material particles and is not merely a disturbance in the ether, as are the radiations. If the emanations are allowed to continue for several days the substance given off proves, on careful investigation, to have the properties of what is known as element helium. This is a material found first in the sun, and hence called helium from the Greek word for sun, but which has since been discovered also on earth. These emanations will not pass through glass, though needless to say the radiations will penetrate it to a considerable degree. The main source of radium is pitchblende, a material found in abundance in Austria but also in various parts of this country. The French physicist Becquerel found that there was something in uranium derived from pitchblende which effected a photographic plate, when presumably the plate was thoroughly protected from chance exposure by a light-tight cover. Madame Curie, in the course of some investigations of pitchblende, found a substance even more radio-attractive than uranium and, later, discovered radium. At the present time it seems not unlikely that radium is a definite element, though probably polonium is only a chemical compound with borrowed radio-active

properties. It has been thought to be a disintegrating product of radium, or a radio-active compound of bismuth, or tellurium. The fact of radiation can be discovered by means of a photographic plate, but the amount of radiation is much harder to determine. By means of an electrometer, however, substances having radio-activity up to 100,000 or even 200,000 Ms. as the term is, that is, having that many times the radio-activity of the same amount of uranium taken as a unit, can be measured. For higher powers of radio-activity chemical data are the only ones available.

Glow in Darkness.—Neither the emanations nor the radiations of radium are properly responsible for its glowing in the dark. This may be due to the presence of some other substance, such as barium. It may, however, be due to the effect of radium on the nitrogen of the air. The spectrum of the glow of radium is almost the same as that seen from nitrogen under certain conditions. Radium has the power of exciting fluorescence and phosphorescence in other substance. As a sequence of this the placing of a phial containing some radium in water was supposed to render the water radio-active. This was claimed to have possibilities of wondrous effects in medicine. These claims, however, are absolutely groundless. No radio-activity can be produced by the exposure of water to radium in this way.

Absorption of Rays.—Radium kept in glass tubes is not in the most favorable condition for it to exert its activity, since the glass absorbs most of the radiations. Besides, if there is the slightest flaw in the glass, the emanations from the radium gradually force their way through and for a time the metal loses its radio-active power. Aluminum makes a much better container than glass, for such a tube will not rupture, but the emanations succeed in leaking through even the pores of the aluminum. Hence the aluminum tubes are enclosed in silver tubes. Something of this difficulty can be overcome by an arrangement to modify electric tension by sealing a platinum wire into the tubes.

New Elements.—The discoveries with regard to radium and cognate substances have given rise to new enthusiasm for certain forms of chemical investigation. As the result two new substances, carolinium, named after the State of North Carolina, and berzelium, called after a Swiss chemist, have been discovered in thorium. These are the radio-active substances in thorium, which is very familiar as the substance that glows in Welsbach mantles. Pure thorium itself is not radio-active. Physical investigations have also shown a number of interesting facts. Alpha rays are very probably positive electrons, that is, material particles having about twice the size of the atom of hydrogen. Beta rays, on the other hand, are subatomic bodies, negative electrons having a constitution about equal to 1-1000 of an atom of hydrogen. Gamma rays are undulations in ether and are probably not corporeal. The beta rays or negative electrons have the same character, in Dr. Piffard's opinion, as the cathode rays, but have a greater velocity. It is the cathode rays that occur with the X-rays which Dr. Piffard believes to be the cause of the so-called X-ray burns. Radium itself is really a transcendentalized pocket edition of the X-rays. The substance to be obtained with any assurance must be bought of a reliable firm, for Dr. Piffard has found that in one place at least radium sold as having forty M radio-active power, proved, on investigation by himself and confirmation by Madame Curie's laboratory, to have less than one M of radio-active power.

Therapeutic Value of Radium.—Dr. Robert Abbe said that as the result of the reaction from the exaggerated claims for the therapeutic effect of radium there has come a state of nihilism with regard to its effectiveness in medicine and surgery. Dr. Abbe, however, is firmly convinced from personal observations that there is much in radium that is likely to be useful especially in surgery, and considers that it would be a great misfortune if its investigation was to be given up. It is a very subtle powerful agent acting on cellular energies in remarkable ways and coming somewhere between the X-rays and Finsen rays in efficiency as regards modification of biological processes. The study of its effect on cell life is very striking. If twenty seeds be exposed for four days near a tube of radium and twenty other seeds for two days and twenty further seeds taken as controls and all sixty planted, those that have been exposed to the radium will be very much retarded in their growth, the seeds that have been longest exposed being most retarded. Just what has taken place in the seedling is very hard to determine, but the effect is easy to see.

Effect on Animal Life.—If the grubs of certain insects be exposed to radium a very curious result ensues. Some of the grubs will die, others, however, will be rendered somewhat sluggish in their movements, but the most curious effect will be a failure to go through the ordinary transformations which would make of them successively pupæ and winged insects capable of reproducing their species. If meal worms, for instance, are exposed to radium for some time, intsead of entering on the pupa stage and then developing into beetles, they will remain as meal worms and continue to feed, while control meal worms that have not been exposed to radium will become beetles, laying eggs which in turn become meal worms and then beetles for three or more generations. The original exposed meal worms are still alive—Methusalas of their species—showing no tendency to go through the cycle of development natural to them. These facts are most interesting for the physiologist and for the physician and surgeon who are brought face to face with the problem of the reduplication of cells which brings about the process known as malignant growth.

Effects on Healthy Skin.—Dr. Abbe exposed the healthy skin of a patient suffering from slow running cancer, which did not require immediate removal to the action of radium. The result was a destruction of cells for a quarter of an inch beneath the radium. In portions of tissue affected by the malignant growth the nests of cancer cells were found to be disorganized and destructive necrosis with liquefaction or melting away of the cancer tissue was found to have occurred. In a large recurrent nodule of carcinoma, nineteen applications of radium in a period of three months reduced the growth to one-third of its original size. A portion of this removed, showed the occurrence of fibrous induration and a great reduction in the number of nests of cancer cells, though some of the true cancerous material still remained. In the treatment of a giant-cell sarcoma of the lower jaw in which only a shell of bone was left and three teeth were loose, exposures to radium, the tongue being protected by lead, gradually brought about great improvement. The exposures were made three hours at a time for fifteen applications and the patient is now apparently cured. The progress of the disease has ceased and its growth has been retarded evidently in something of the same way as that of the seeds and the meal worms.

Other Therapeutic Uses of Radium.—Some milder affections yield promptly to radium. Dr. Abbe has seen a case of long-standing lupus cured by one application. Warts can be made to disappear like magic after a single exposure to a reasonably strong radio-active sample of radium. Nests of warts such as

occur in certain persons, have been made to disappear in four applications. The use of it produces a retrograde metamorphosis that leaves absolutely no scar after it and gives the best possible cosmetic result in such cases. Dr. Abbe has found this true also with regard to cancer nodules and in the case of the sarcoma of the jaw. The result is better than could possibly be obtained by any surgery, however careful. Of course it is possible that growths may recur. The use of radium repeated will doubtless do what it did at first; if it does not, then something can still be accomplished by the use of the knife and the patient is, as a rule, in no worse condition than at the beginning of treatment.

Radium and Parthenogenesis.—Dr. Piffard, in closing the discussion, said that undoubtedly investigation will bring out very clearly the value of radium. The present nihilistic reaction is unfortunate, but is as far from the truth as the exaggerated significance originally given to the material. To offset Dr. Abbe's description of the effect of radium in retarding reproduction, Dr. Piffard said that it had been found that the exposure of certain of the ova of the lower animal forms to radium brought about their growth without conjugation,—that is, gave examples of parthenogenesis where normally these did not occur. This is of course only what Professor Loeb succeeded in doing with certain chemical irritants at the University of Chicago, but it shows the profound modification of biological processes that may be brought about by radio-active influences.

BRITISH MEDICAL ASSOCIATION.[1]

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

(Continued from Page 384.)

In the newer ships refrigerating rooms are now supplied, and by this means fresh provisions may be carried, especially for short sea trips. As regards the nutrient value of the naval dietary, if one only takes the daily ration of beef, bread, vegetables, and sugar, each man is supplied with 291 gr. of nitrogen and 5,425 gr. of carbon; this, with the other ingredients of a sailor's dietary, comes well beyond the limit laid down by Parkes and Playfair of 307 gr. of nitrogen and 4,700 gr. of carbon, which an average man gives off in a day. It is also very much beyond the scale allowed to convicts doing hard labor (263 gr. of nitrogen and 5,003 gr. of carbon).

Meal Hours.—Since October 1, 1903, the Admiralty have recognized five meal hours, the aggregate time allowed being three hours, thirty-five minutes, instead of two hours, thirty minutes allowed by the old system for three meals. The meal hours are: An issue of cocoa on turning out at 5 A.M.; breakfast at 8 A.M.; dinner from 12 to 1:15 P.M.; tea at 4:15 P.M.; and supper at 7:30 P.M. These hours are very well arranged. In the tropics it is customary to have a two-hour dinner hour, with light work afterwards, the heavy drills being got through as a rule before breakfast.

Medical Officers with Regimental Unit in the Field.—Major T. D. F. Donegan said that the distribution of medical officers in the field is, to say the least of it, a difficult problem and one which requires a great deal of thought and consideration. In the various returns which go in to higher authorities the allotment of these officers is referred to, and it is quite natural to suppose that a practical distribution may not appear to be a right one to officers far away in a high administrative capacity. The senior medical officer of a force should have power to utilize his medical officers as he thinks best, and to send them where they are wanted, instead of the present cast-iron allotment per regiment. The duties of a regimental medical officer in the field are as follows: (1) To be with his unit under fire in charge of regimental bearers; (2) to see the morning sick of his corps, and to send such sick, other than those suffering from minor ailments, to the brigade field hospital; (3) to attend to the sanitation of the camp, as far as it pertains to his own unit. Now the first of these is to his mind the most important duty, therefore if the unit is not likely to be detached by itself it does not require a medical officer, as its sick could be seen by the nearest bearer company or field hospital, sanitation could be attended to by a brigade sanitary officer, and its actual wounded in the field could be looked after by the bearer company. His proposal is the modified one as follows: With an ample supply of medical officers, when the establishment of bearer companies and field hospitals is complete, when casualties in either of these units are provided for, then to post to each unit a surplus medical officer on the understanding that his appointment is temporary and that he can be withdrawn the minute he is required elsewhere. As regards the equipment issued to these officers, it is at present excessive. Field panniers with operating cases are cumbersome, unnecessary and useless, as assistance is always required before any operation can be done. As the hospitals or bearer companies are the places for operations there is no necessity for a single medical officer to carry, regimentally, the equipment necessary for amputation at the hip-joint, as the only thing he may ever have to do single-handed would be the ligature of an artery, and, perhaps, the relief of a strangulated hernia. If the present field panniers contain more than is necessary, the field companion (and its own companion the water bottle) is hardly enough. In his report on the Eighteenth British Field Hospital in South Africa, he suggested that the regimental medical case should contain as follows: Modern tooth instruments, a surgeon's pocket case, some Spencer Wells forceps, retractors, tourniquets, ligatures in bottle, chloroform in capsules (as used by Boers), two waterproof sheets, two small dressing trays, some antiseptic tabloids, adhesive plaster, bandages and dressings, and syringes. For medical assistance the following may be added: Two thermometers, one aluminum stethoscope, one hypodermic syringe, with spare needles, a tabloid case of medicines, and a strong candle reading lamp, some spare bandages in waterproof bags, some surgical dressings, and some medical comforts would also be required.

He further spoke of hospital and ambulance service equipment.

Sterilization of Infective Discharges and Utensils on Field Service.—Lieutenant-Colonel A. M. Davis, in dealing with this question, said that the best mode of dealing with infective discharges, when on active service in the field, will probably vary according to circumstances; it will not be advisable to lay down one hard-and-fast rule to be of universal application. The four following methods are the only ones that are likely to be carried out in practice: 1. Burial in earth, either in deep or shallow trenches. 2. Treatment with disinfectants, followed by burial. 3. Sterilization by moist heat, followed by burial. 4. Destruction by fire—that is, incineration.

(1) Burial in shallow trenches (less than 24 inches in depth) is better than scattering the dejecta about on the surface of the ground, but is not to be recommended if it can possibly be helped. Burial in deep trenches (over 2 feet) is not so likely to pollute the

[1] From advance sheets of the *British Medical Journal*, by courtesy of the editors.

air, but will pollute the soil quite as much as burial in shallow trenches; indeed, more so, and for a longer time; this also is not to be recommended.

(2) Treatment with disinfectants, and then burial, lessens the risk of polluting the soil and air; but it is difficult to ensure their thorough application to solid excreta, and the length of time required for the complete action of moist disinfectants (necessitating the retention of the excreta for perhaps some hours) causes great practical inconvenience. Although better than simple burial, this method is not to be recommended if it can be helped.

(3) Sterilization by moist heat—that is, boiling—is undoubtedly efficient. All pathogenic bacteria that come under practical consideration are entirely destroyed by a temperature short of boiling. Solid and liquid excreta, infected ablution water, utensils of all kinds that have been fouled (bedpans, urinals, spitcups, etc.)—in short, everything that is infective can be rendered innocuous by this method. Two points are to be borne in mind. (1) the quantity of fuel required is large; and (2) the material disinfected (or at any rate a considerable proportion of it) remains to be disposed of, by burial or otherwise.

(4) Destruction in a furnace, that is, incineration, also requires a considerable quantity of fuel; but the offensive matters are rapidly and completely destroyed, leaving nothing that needs to be removed for burial. This method is equally as efficient as the last mentioned, so far as it goes; and the choice between the two resolves itself into a comparison of (*a*) quantity of fuel required, (*b*) extent of applicability or degree of usefulness, and (*c*) ease and inoffensiveness of working in each case.

(*a*) The quantity of fuel required should be less in the case of a destructor or incinerator than in the case of a boiler, because dry rubbish of all kinds can be used as fuel for a destructor. The saving of fuel is, however, not so great as might be expected, because (1) the temperature to be attained in a boiler is only 212° F. (=100° C.) at the most, while in a destructor a temperature of at least 850° F. (=450° C.) must be reached in order to actually burn up the material. (2) The presence of even a small quantity of moisture in the substances to be burned adds largely to the quantity of heat required (that is, fuel necessary); for, whereas to raise a pound of water from the ordinary temperature (say 15° C.) to boiling temperature (100° C.) requires 100—15=85 units of heat, to convert that pound of boiling into steam (which, of course, is a necessary preliminary to incineration) requires 537 units of heat, making a total of 85+537=622 units of heat. (3) If incineration is attempted, the high temperature must be maintained until everything is burned up, which in practice leads to the consumption of a great deal of fuel, much more than the theoretical quantity required; in the case of boiling when the temperature is once reached, a very small amount of fuel is required to maintain any given quantity of water at that temperature. From these considerations it appears that the saving of fuel would be slight, if any, in the case of incineration.

(*b*) As regards extent of applicability, or degree of usefulness:—Boiling renders harmless (1) all infective discharges of whatever description, liquid or solid; (2) infected ablution water; (3) infective utensils; but it does not deal with (4) ordinary non-infective excreta; nor with (5) rubbish or dry refuse; and (6) the infected discharges and ablution water remain (after disinfection) to be taken away and buried, or otherwise disposed of. A considerable proportion, however, of the fluid is got rid of in the form of steam.

Incineration destroys (1) all rubbish and dry refuse matter; (2) solid excreta, both infective and ordinary: and (3) some proportion of the liquid excreta (the amount depending on the size of the apparatus); but it does not deal with (4) infective liquid discharges, urine, etc. (if large in amount); nor with (5) infected ablution water; nor (6) infected utensils.

Ablution water and slops must, however, necessarily be removed from the immediate neighborhood of a properly managed hospital, in any case; and it is certainly better that they should be removed in a disinfected than in an infective condition. It is true that liquid disinfectants might be used to render them innocuous; but disinfection by heat is safer, and where fuel is procurable is to be preferred. The same may be said in regard to utensils. Assuming then that liquid sulliage has to be removed in any case, the additional bulk of material to be removed, if boiling be the method adopted, (that is, solid excreta that would otherwise have been incinerated) is practically negligible. There remain the cost and labor of removing rubbish and dry refuse, and ordinary non-infective solid excreta; this has to be set against the cost and labor of their incineration.

(*c*) As regards ease and inoffensiveness of working: Indian experience is unfavorable to the use of incinerators for destruction of excreta; very numerous patterns have been tried during the last fifteen years, and in no case has a thoroughly satisfactory result been obtained. In South Africa, however, they were used with success in many instances. But the preponderance of medical opinion, derived from South African experience, appears to be in favor of boiling as compared with incineration.

In circumstances where fuel is scarce, any form of heat disinfection may be impracticable; in such cases, deep burial, after treatment with chemical disinfectants, is to be recommended for infective discharges, etc. But if fuel is available, moist heat (that is, boiling) appears to be, on the whole, preferable to dry heat (that is, incineration).

The apparatus that has been devised by Major H. A. Cummins, C. M. G., R. A. M. C., for disinfecting excreta and utensils by boiling, is convenient in form, portable and easily worked. There is no smell during the process of disinfection. It is estimated to be capable of dealing with the excreta, slops and bedpans, of about 100 acute cases of enteric fever during the twenty-four hours. Its weight is 2 cwt. 3 qr. 24 lb. (say 3 cwt.), and its over all dimensions are 3 ft. 6 in. by 4 ft. 9 in. Experiments have shown that in ordinary weather about 50 lb. or 60 lb. of coal suffice for a working day of eight hours; in windy weather about 80 lb. of coal are required. Wood or other fuel may also be used.

The Recruiting Problem.—Major W. C. Beevor, in a paper on this subject, brought out the various difficulties encountered in Great Britain. As the problem is distinct from the American problem, we omit further consideration of his interesting and suggestive paper.

(To be Continued.)

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, April 7, 1904.

The President, Dr. R. C. Norris, in the Chair.

New Operation for Puerperal Sepsis.—This paper was read by Dr. Swithin Chandler, who, after making a few preliminary remarks regarding the causes of puerperal sepsis, described his new operation for puerperal sepsis as follows: Make an incision posterior to the cervix in the posterior vaginal wall; then pass a pair of long blunt-pointed forceps, slightly curved, in the cervical canal, up into the cavity of

the uterus; then puncture the posterior wall of the uterus in the center near the top of the uterus. Then introduce with two fingers a piece or strip of iodoform gauze in through the posterior vaginal opening previously made, clasp the gauze with the forceps and drag the same through the uterine wall and out through the vagina. Repeat this by puncturing the uterus on each side, but posterior and just about the middle of the body of the same, drawing the gauze through the same as in the first attempt. Thus one will see the uterus is treated as a thoroughly infected organ deserving heroic treatment. He then gave a few statistics regarding the mortality of other operations in puerperal sepsis. The objections which he thought might possibly be offerred to his operation were: (1) All cases are not those of virulent infection; (2) it causes additional injury to an organ infected; (3) curettage and removal of membranes are often sufficient; (4) it may so injure the uterus as to interfere with labor.

Regarding the first objection it is admitted he would not always advise its immediate undertaking. As to the second objection, while it makes more injury, no hesitation is felt in opening an infection in other organs, and one has no more infection, and experience in this operation is similar to operation in other parts. To the third objection, as to the first, he would answer, if one is prepared to operate immediately if required, well and good. In answering the fourth objection, as yet he cannot say, but he does not believe it would have any bad results, especially after knowledge of how the uterus is treated by the inexperienced in curettage, removal of growths, etc. In favor of the operation Dr. Chandler claimed the following: (1) It is conservative; (2) it is by the experienced easily performed; (3) it is logical, because it treats the organ as an infected part, gives drainage to the uterus and those tissues and vessels shown by post-mortem examinations to be affected; (4) the mortality is greatly lowered, and it gives far superior results so far, although its exact results must yet be proven by a larger number of cases than as yet I have practised upon.

Dr. Chandler closed his talk with a report of a few cases operated upon in the manner above described, a description of the results obtained, etc. (See MEDICAL NEWS, August 6, 1904, for Dr. Chandler's paper.)

Dr. George M. Boyd said, in the discussion, that every contribution to the treatment of puerperal sepsis is of interest. He said that this method and the method which has been described by Dr. Pryor had seemed, in his opinion, heroic treatment in this class of cases. We occasionally have a death from puerperal sepsis, but the majority of cases recover. Many of the bad cases have a general systemic infection with only a local manifestation of infection. In the cases that have not recovered he has felt that the infection was beyond the uterus and that the patients died from a general systemic infection. He is not prepared to endorse the operation that has been suggested.

Dr. W. Reynolds Wilson, in the discussion, said he had always felt that the way to approach this subject is from the point of view of diagnosis. To be sure, there are cases that are desperate, and cases which will require what Dr. Boyd has chosen to call heroic measures, but it is very difficult to diagnose such cases in time to carry out such an operation. The bacteriological study of the case, he thinks, is extremely important. The localized pelvic infections with the presence of the staphylococcus and lympatic engorgement involving the parametrium are cases which in the beginning present very severe symptoms, but which when properly treated by non-surgical means usually make a very rapid recovery. At the same time it is difficult to differentiate these cases from cases of overwhelming rapid infection, infection which begins early and which spreads into the system before we are able to institute any local treatment. That being the case, it seems to me there is required a very acute knowledge of the course of such infection, a knowledge which most obstetricians will find it very difficult to get. He thinks there is not enough infection nowadays to make it possible to draw the fine lines in diagnosis. He can understand perfectly well that the uterus may be the site of infection, that pelvic drainage may in certain cases interfere with the further spread of the disease. At the same time his mind is recalled to the first case that Dr. Chandler described, in which a mass of the placenta was removed under ether and in which he performed the operation. In that case it would be extremely difficult to tell whether the removal of the placenta itself might not have been sufficient to relieve the symptoms altogether.

Dr. R. C. Norris, in the discussion, said he had listened very carefully to Dr. Chandler's paper, and he thinks its gravest defect is his failure to indicate the class of cases requiring this kind of treatment. The same objections, intensified, are applicable to this treatment as to Pryor's operation. Pryor distinctly limits his to streptococcic infection, Dr. Chandler only speaks of "grave" cases. For cases of puerperal infection in the early stages, when it may be that the case is one of sapremia, which promptly recovers after clearing out of the uterine contents; for general blood or lymphatic infection and for uterine phlebitis Dr. Chandler surely would not resort to this measure and hope for success. If the infection is a virulent streptococcus and has passed beyond and is not confined to a localized area in the pelvis, as so frequently happens, surely this plan of treatment would not avail, as hysterectomy and the use of curettage have failed, as Pryor's operation has failed and as every other surgical operation has failed. Dr. Norris thinks Dr. Chandler should specifically state the class of cases in which he would consider this operation necessary; and he would be glad if he would furthermore point out to the obstetrician in what way these perforations of the uterus can accomplish drainage of that organ more efficiently than an intrauterine gauze drain. Dr. Norris is convinced that there are very rare cases of beginning peritoneal infection following abortion and labor, due to leakage from the tubes, that culde-sac drainage might save, if we could diagnose them by any means, clinical, bacteriological or otherwise. If the channels could readily determine through which the infection is spreading and how far it has spread, the obstetrician would know when and what cases to drain and attempt to avert a fatal termination. So far as his experience goes, that cannot be determined. He has gone over this ground in the discussion of Dr. Pryor's paper. Until Dr. Chandler designates more certainly in what class of cases he advocates the use of this methods, Dr. Norris thinks it is distinctly dangerous teaching. He speaks of it adding to Dr. Pryor's operation in that the uterus is also drained. The uterus can be drained as efficiently and certainly with less danger without making useless perforations through the uterus into the peritoneal cavity. Gauze passing from the cavity into the vagina will drain the uterus as well as three pieces of gauze that perforate the uterus and pass into the peritoneal cavity, without the serious danger attendant upon the latter. He cannot conceive why any one would perforate the uterus, expecting to secure better drainage of the uterus. He can see no advantage and only dangerous surgery in the operation, and he would like Dr. Chandler to convince the obstetrician that his

patients recovered because of and not despite his operation. Dr. Norris feels that he adds grave danger by carrying from an infected uterus a gauze drain into a peritoneal cavity that may be free from infection. His judgment is that it adds a distinct risk in the treatment of any case. He should feel quite as inclined to treat a case in this manner as he would, in a case of beginning sepsis, to open the abdomen and cul-de-sac and insert a loop of gauze with the hope of saving life. If it is drainage we are striving for, why stop with the uterus and cul-de-sac? We must remember that drainage is not going to save every case of sepsis. It is utter folly to attempt to drain the pelvis or even the uterine cavity if the infection has already spread beyond. It is risk enough to open the cul-de-sac, but this is doubled by perforating the infected uterine wall and inserting gauze into the peritoneal cavity. Dr. Pryor's operation is only done in cases of streptococcic infection. Its employment is based upon bacteriological study and he has limited his cases to that class. Dr. Chandler has not done so. He simply speaks of "grave infection." The mere finding of streptococci does not tell how virulent the case is. Dr. Norris has repeatedly found streptococci in the uterus after labor when the woman had no fever. He has also found them in women who had fever and who got well. The mere finding of organisms is not enough; the difficulty in selecting treatment depends wholly upon the question of diagnosis spoken of by Dr. Wilson. There are no means to predict the outcome in individual cases, no means more reliable than clinical to differentiate the gravity of our cases, and until that can be done, this method of relying wholly upon drainage and running the risk of infecting the peritoneal cavity should not go unchallenged. He considers it dangerous practice and believes that it would lead, in a large number of cases, to increased mortality. Relatively few cases would be saved by vaginal drainage, and these few would just happen to be appropriate cases operated upon at the right time. We have no accurate means of determining the appropriate cases early in the course of the disease and when that right time arrives. He thinks a word of caution should be sounded, and that the obstetrician should reserve pelvic and abdominal surgery for puerperal sepsis to cases with distinct localized lesions. To open the cul-de-sac or perforate the uterus and pack with gauze where no evidence of infection outside of the uterus exists, or when evidence does not exist that infection has spread to the lymphatics or venous systems, is the height of folly. The obstetrician should confine pelvic surgery in puerperal sepsis to localized infections. When no localized infection exists this method is unscientific. Even with the most skilful bacteriological examination we could not predict in any case whether it is a type of case that pelvic drainage will save. If Dr. Chandler operates upon a case when the infection has passed beyond the uterus and pelvic cavity, he helps the patient not one iota by opening the cul-de-sac, perforating the uterus and dragging three pieces of gauze from the opening in the vaginal vault, through the uterus and the cervix, making a U-shaped drain. If the infection is localized in the uterus the patient runs the risk of septic peritonitis, from which she may die, as the direct result of this treatment.

Dr. W. Reynolds Wilson, in the discussion, supplemented his remarks by stating his experience in hospital practice with cases of infection. He does not believe that one-half per cent. of the cases that begin as infected cases go on to septicemia, that is, to a fully developed systemic infection. The class of cases that it has been his experience to deal with have been: (1) Putrefactive cases, in which there is intoxication from retained débris within the uterus. That is the common class of cases which he has observed. (2) Cases of parametritis, a simple lymphangitis, with edema of the broad ligament. In this class the expectant treatment has always been satisfactory. (3) Cases of the gonorrheal infection. These are the common cases in his experience based upon a more or less extensive observation, and in every one of such cases, were such treatment resorted to, the chance of streptococcic infection of the peritoneum would be imminent.

Dr. B. C. Hirst, in the discussion, remarked that he would like to add a word of condemnation of this proposition of Dr. Chandler, which cannot be based on such practical experience, and which is, Dr. Hirst thinks, distinctly dangerous. Indeed, it is difficult to criticise it as severely as it deserves, and yet to observe the courtesy of debate. He should object to a proposition of this kind appearing as read before the Obstetrical Society, unless accompanied by the criticism which is sure to follow. Dr. Pryor's proposal to drain the pelvis, to which Dr. Norris has referred at length, is more rational than is Dr. Chandler's, but it is founded on incorrect premises, and is not, to Dr. Hirst's thinking, the result of sufficient clinical experience with all forms of puerperal sepsis, and is wrong in principle. Dr. Hirst said he performed a good many exploratory incisions, especially in the early history of the operative treatment for puerperal sepsis. When in doubt in a case of metritis, whether the inflammatory product is in the uterine wall and is about to break into the peritoneal cavity, or whether it is contained within and limited to the wall, he still resorts to an exploratory abdominal section, as he also does in cases of pelvic cellulitis, to be sure there is no intraperitoneal involvement. From a considerable experience, therefore, in the inspection of the pelvic cavity in cases of sepsis, he is in a position to say that Dr. Pryor's premises on which he bases his procedure for opening the vaginal vaults are incorrect. The pelvic peritoneum is not immediately invaded in streptococcic infection, and is usually never invaded at all. Dr. Hirst has seen a number of cases of the gravest infection in which there was no involvement of the pelvic or abdominal peritoneum. The pelvic peritoneum is often entirely unaffected, and there is no serum in the pelvic cavity. If, therefore, Dr. Pryor's procedure is incorrect, Dr. Chandler's, he thinks, is totally unwarranted. The former will occasionally be followed by fatal peritonitis, which could otherwise have been avoided; the latter, if ever actually tried in practice, would be even more likely to cause death in this way.

Dr. F. H. Maier, in the discussion, said he did not hear all of Dr. Chandler's paper, but from the remarks of Dr. Norris he has gleaned the principle of his procedure in this class of cases, and he agrees with Dr. Norris that it is not one to be allowed to go unchallenged. Concerning Dr. Pryor's operation, there is no question in his mind that in a certain class of cases it is a most valuable procedure. Dr. Maier is inclined to think that in a certain number of systemic infections the lower pelvic cavity acts as a breeding focus from which fresh poison is sent out into the system. By opening into Douglas's cul-de-sac the obstetrician undoubtedly corrects a condition that would otherwise cause the death of the patient. And these are the cases, until the profession has better means of satisfying itself that there is nothing in Douglas's cul-de-sac, in which it will be good practice to drain.

Dr. Norris asked Dr. Maier how he would recognize that class of cases.

Dr. Maier, in answer, said until the profession had better means of recognizing this class of cases in which infection in Douglas's cul-de-sac with systemic infection was had, and where it does not respond to expectant treatment, he thinks it is well to make such an incision. He thinks there is very little danger and much good can be accomplished. He remembers one case a year ago, in which the attending physician had cleaned the uterus a week before. The case was brought to the hospital, and he thought the attending practitioner had not done a clean job. On going into the uterus, however, there was nothing there. Then a vaginal incision was made, and an opening into Douglas's cul-de-sac, and a lot of dirty serum was found. No cultures were made to demonstrate the organisms. The patient recovered after a protracted convalescence. In certain cases where the profession intuitively feels that something must be done, he feels that the Douglas's cul-de-sac can be opened with little added danger. He thinks the risk is worth the doing.

Dr. B. C. Hirst, in the discussion, said he would like to ask these gentlemen, particularly Dr. Chandler, what proportion of cases they think are infected in Douglas's pouch. A large experience is needed to decide this question. He thought the president, and himself, who had charge of large maternities, and who saw scores of these cases to one that is seen by the general surgeon or the gynecologist, without experience in obstetrics, were in a position to make a statement on the subject. He has rarely seen infection in the puerperium confined to Douglas's pouch. He had to operate on a large number of these cases every year. He doubts if any clinic in America had a larger number than his. In the last three days three of the most desperate cases of puerperal sepsis were brought into the University Hospital in the ambulance. He has usually four to six such cases under observation continually. Out of a large number, every year, he sees a very small proportion in which the infection is localized in Douglas's pouch. When one can determine its localization in Douglas's pouch by easily appreciable physical signs, the obstetricians all agreed that colpotomy is indicated, but to do this operation as a routine measure, simply because one don't know what else to do, and feels that something must be done, is a proposal discreditable to surgery.

Dr. Chandler said, in closing the debate, one would naturally think after the remarks which have been made that there would be some hesitation on his part, but so convinced was he that the operation is a logical one, that the opposition expressed only caused him to uphold it more zealously than had such opposition not manifested itself. He answered the arguments in their turn as they have been propounded by the different physicians present. In regard to the criticism of Dr. Boyd, he would state that the text of his (Dr. Chandler's) paper contains the answer. It is that the operation is advised in severe cases, or cases that in one's judgment are liable to become severe, and the paper states that the operation would not be employed in cases of mild infection or infection with the colon bacilli or with the gonococcus. It is only in the streptococci cases that the operation is advised. In regard to the second point, Pryor has reported cases in which he has operated, and in which the temperature fell immediately, and the patient recovered, showing that there was no systemic infection, or that it was not of such character that it killed the patient. And his operation, which in Dr. Chandler's judgment lacks some of the better qualities of the one suggested here to-night, has produced good results, unless one says that Pryor did not tell the truth, and he (Dr. Chandler) is not prepared to make or even insinuate such a statement, and would refuse to believe a statement of that kind. Dr. Wilson spoke of cases of infection being very few, thereby intimating that the operation was for some obscure trouble, yet Dr. Hirst, in his discussion to-night, has stated that three cases have just entered the hospital with which he is connected. This, in Dr. Chandler's judgment, answers Dr. Wilson's question. While not altogether bearing on this point, and yet he feels it is apropos, he would like to say that there is a habit in discussing the cases in our city societies of citing only the cases which occur in the city, omitting any that occur in the country and suburban districts. What is applicable to the city in regard to the number of cases and their causes, etc., of disease, is not always applicable to those of the country, and vice versa. He would state, however, that he believes more of these cases occur in the country and in smaller towns than in the large cities. This is not in any way a reflection against the judgment and skill of the country practitioner. But he has such distances to travel and so many hardships with which to contend before reaching his patient, that in spite of his skill and judgment more cases do occur in his practice. Dr. Wilson spoke of the removal of the placenta in one of Dr. Chandler's cases. It is true, no one can say that the case would not have recovered with this simple removal, and it may be that the point is well taken. Dr. Norris has asked an important question: When do these cases need the operation? Dr. Chandler would answer that by asking whether Dr. Norris, or any other doctor, can always tell when a patient is ill from any trouble, when in the exact time, or what is the exact basis upon which to determine operating. Just as in Dr. Keen's paper on "Massage of the Heart," when he (Dr. Chandler) asked him how long he would wait before performing massage of the heart, he said that it was not time that was to be considered, but after a certain lapse of time, probably five or ten minutes, but he would not be held to that, as it was the general condition of the patient and other matters which would determine whether he would perform massage of the heart. With all things given, with the respiration over 44, and with an infection streptococcic in character, Dr. Chandler would not hesitate to do this operation, bearing in mind the general condition of the patient in this advice. The reason he spoke of respiration is because he believes this is a valuable indicator in this as well as in other troubles. A case was just brought into one of the hospitals, and after being there some little time was seemingly recovering, and on the day before the patient died the temperature had fallen to 98.2° from 104° F.; the pulse was almost normal; everything except the rapid respiration, which was between 50 and 60, pointed to recovery, and yet within a few hours the patient was dead. Dr. Norris also asked how this operation would give additional drainage, and why the operation was more logical than that of Dr. Pryor's, which seemed to him to be the more logical of the two. In the first place, the operation of Dr. Pryor's is not an operation of drainage, and he (Dr. Chandler) could not conceive that it does drain to any extent. On the other hand, if one considers the lymphatic system around the uterus, consisting of a jacket of lymphatics leading to two different trunks or cords which lead from the region of the cervix out through the broad ligaments, and nearer the fundus of the uterus, those forming a complete network of lymphatics surrounding these parts and leading from these parts to the general lymphatic circulation, he thinks the logic of how additional drainage is obtained is evident. The moment that one punctures clear through the uterus one punctures these channels, thus making open-

ing through which free drainage can occur. The operation is surely much more practical on account of this drainage than that of hysterectomy, which has been done with a mortality of 55 per cent. in selected cases. Dr. Norris also spoke of immediate spreading of infection. Dr. Chandler thinks this is one of the best arguments for the operation, for if it did not spread through all the lymphatics immediately, one probably would not be justified in performing the operation, because one might be the means of spreading such infection by injuring the uterus and its tissues, but since it is already infected that argument loses its force. Jacoby has reported 51 cases which were selected, every one of which showed infection of the lymphatics. Dr. Norris asks what Dr. Chandler means by "extremely severe cases." This is a point well taken. He (Dr. Chandler) cannot answer this otherwise than he has, except by saying, generally speaking, when a case had reached the danger line. There are some cases overwhelmed by infection in which one cannot tell the result. The profession has seen them go to the danger line and then recover. It may be that the lymphatics here may be more numerous than the lymphatics in other local parts, still one does not have any more general systemic infection following this operation than one has when entering other parts for operation, when such parts have been infected. Dr. Chandler remembers Dr. McLane Tiffany, of Baltimore, speaking before a meeting of railway surgeons several years ago, make the statement that the only way to cure a macerated kidney, or to save a patient, was to boldly cut into the kidney. Dr. Chandler thinks there is not a man in the country who would hesitate to do this now, nor would he admit that he would have more infection than if he did not so cut into the kidney, and in that case, as in these cases of sepsis, he probably would have death if he did not do so. In regard to bringing forth a warning, no one desires to protect the medical fraternity and the patients more than Dr. Chandler, but in these severe streptococcic infections, with a respiration over 44, and with every sign of collapse, with the full knowledge that every lymphatic in that part is infected, and he defies anyone to bring a case here that differs from those reported by Jacoby, he cannot see why any cry of warning is needed. On the other hand, he can see why it is wrong to stand by with a full knowledge of the case, and say one cannot operate, because one may make further infection, and this when the infection is upheld by every analysis and all the statistics that the profession has at its hands.

In regard to Dr. Hirst's remarks, his speech of condemnation is one only of condemnation to my mind, and not one of logic. He demonstrates in his text-book that in these conditions the uterus is a generally infected organ, and in this text-book he displays a uterus which he has removed in hysterectomy—the uterus seared from top to bottom. Both the picture and his description of the uterus leave their impression upon the mind, and Dr. Chandler would ask him how in the name of common sense is one going to reinfect an organ of that kind, and how much more logical is the operation which he has proposed than the one which he and others at one time advocated, that of hysterectomy, for in hysterectomy, in tying the uterus one ties up the lymphatic trunks or cords, thus tying up the lymphatics which have been infected so that the poison absolutely cannot get out, tying them up in a bag, as it were, with the result that the only exit that they have is in the general current, and, if possible, the result of a stronger and, therefore, a more virulent general infection. The mortality in hysterectomy, as has been mentioned before, in selected cases, is admittedly 55 per cent.

Dr. Chandler thinks too serious a view of this operation is taken. He believes that when it is realized that the uterus is a thoroughly infected organ, it is too serious a view and one not based on mature judgment and thought to speak of sending out warnings, and not desiring that this society should bear the burden of any such operation, as the gentleman has remarked. In answer to Dr. Hirst, Dr. Chandler thinks the operation he suggests is a logical one, because it does drain, and that is the endeavor to be accomplished, and he has tried to the best of his ability to demonstrate how it does cause such drainage. He will again call to the minds of the obstetrician the position of the lymphatics as they leave the cervix and uterus, and as they surround the uterus, and ask if there is any other method to drain, and is there anything more logical than to drain an infected organ. Again, if the organ has been generally infected, and that much be admitted, what can be the objection to letting out as much of that infected material and its poisons as is possible? In regard to Dr. Pryor's operation, Dr. Chandler does not think Pryor drains his cases. As to the proportion of infection in Douglas's cul-de-sac, it makes no vital difference whether the infection becomes located there or not. It is primarily in the uterus and lymphatics, and in mild cases it may not reach the posterior part of the uterus at all. In severe cases it may not cause an inflammation in Douglas's cul-de-sac, but in other severe cases it does. Patients do not die from infection of the cul-de-sac. If so, one-half of the patients with infected tumors of the uterus and surrounding parts would never reach the operator, because they would have died long before. It is the absorption through the lymphatics and veins that does the damage in these cases. In Dr. Chandler's judgment it is not a vital objection against the operation simply because one cannot tell or give the exact symptomatology when one operates. One might say in any case when to operate, but it depends absolutely upon other conditions present. That is exactly so in this case. In mild cases, with the temperature of 102° or even 103° F., with a respiration of 30, and with no seeming general systemic infection, he would not advise operating, but when a general infection is evident, because mortality in these cases, in spite of what has been said, is high, he sees no reason why one should stand idly by and allow patients to die—and with the results which he has so far obtained, with no logical arguments against the operation, he shall certainly proceed to operate, and will feel no fear of further infection while thus draining the lymphatic system by puncturing an already infected organ.

Tubal Menstruation. Internal Hemorrhage from Ectopic Gestation Without Rupture of the Sac.—The author of this paper is Dr. E. E. Montgomery, and it was read by Dr. P. Brooke Bland. The author reports the history of this case in order to strengthen the argument contained in his paper presented before this society at the October meeting, 1903, on "The Structures Taking Part in Menstruation." At this meeting a case of tubal menstruation was also reported by Dr. Bland. These two papers were written in collaboration. The history of the present case is as follows: The patient was operated upon for laceration of the cervix and a retrodisplacement of the uterus through the abdominal route. The day before the operation the patient's menstrual flow began, and in view of this fact, the author, therefore, carefully examined the Fallopian tubes to determine whether they actually took part in the menstrual process. His finding seemed to indicate that they do really participate in menstruation. In this case the tubes were darkened and congested. Pressure ex-

erted from the uterine toward the abdominal end of the tubes caused a few drops of blood to appear at their external orifices, and also small dark-colored clots were expressed. These were somewhat of the character found in menstruation. The author regrets that a microscopical examination of these clots was not made, because of the possibility of their having been associated with an ovum, and he also regrets that he did not examine the ovaries for indication of recent rupture of Graafian follicles. The case is presented, as heretofore stated, as additional evidence that the tubes are active in the physiological process of menstruation.

In this contribution the author desires to point out the constant danger of tubal pregnancy, in that serious hemorrhage may take place from the gestation sac without fracture of its walls. The first class of cases in which serious hemorrhage may occur without rupture is tubal abortion. Such a condition is usually followed by profuse and dangerous bleeding. The cavity is generally filled with blood which clots, and finally arrests the hemorrhage. Occasionally the separation of the fetal sac may not be complete, but hemorrhage occurs from the partial separation which makes its exit from the abdominal end and causes extensive hemorrhage. Finally, the weakened circulation will result in the formation of a clot which arrests the hemorrhage and saves the patient. The writer cites a case of tubal abortion. The patient had a characteristic menstrual history of pregnancy. She missed two periods, and upon coming under observation had been bleeding for several days. This bleeding was attended with severe pain in the lower abdomen. The patient at times had attacks of cerebral circulatory disturbance. Examination revealed a resistant mass to the right of the uterus. Diagnosis of ectopic gestation had been made, though the author from the appearance of the patient did not think the shock sufficient to indicate either rupture or tubal abortion. The patient was operated upon, and on entering the abdomen, the right tube presented a sac occupying the outer half of the tube, which was filled with clot, but showed no rupture. The fluid had escaped from the end of the tube, but an abortion had not really taken place. The other class of cases to which the author calls attention are those in which the villi of the chorion erode and penetrate the tubal wall, and even its serous covering, and thus bleed from the extremities into the peritoneal cavity. These projections are so small as to often only be perceptible by the microscope, but yet cause dangerous hemorrhage. He cites a case in which this condition was well exemplified. The patient was admitted to the hospital, quite anemic looking, complained of soreness over the abdomen, but had no marked tenderness or rigidity. Examination revealed a retroverted uterus, but little else could be determined. Blood examination showed red blood corpuscles 3,200,000, white 720,000, hemoglobin 70 per cent. Her temperature ran from 99° to 100°F.; pulse 96 to 104. This patient had passed one period but a few days when she was seized with severe pain in the lower abdomen, which was followed by bloody vaginal discharge. This had continued until her admission to the hospital a month later. The patient would at times have rather severe attacks of pain in the lower abdomen, particularly when moving about. At times she also became exceedingly faint and was obliged to remain in bed. She was operated upon, and upon entering the abdomen it was found filled with fluid and clotted blood. The right tube was occupied with a sac about the size of a small orange, which ruptured on being delivered, allowing the amniotic fluid to escape, and not blood. Examination of the sac did not reveal any seat of rupture, except that caused on delivery, but on its surface several small, dark-colored hemorrhagic areas were noted. These upon opening the sac were found to be immediately over the cord or at the placental site. Microscopical investigations revealed that these dark-colored areas were the seat of hemorrhage, and were caused by the villi eroding and penetrating the tubal wall.

(To be Continued.)

BOOK REVIEWS.

The American Year-Book of Medicine and Surgery Edited by Geo. M. Gould, M.D. Volume 2, Surgery. W. B. Saunders & Company, Philadelphia, New York, and London.

This book forms a quite complete record of what has been done in general surgery during the past year. The plan of having specialists in charge of departments has been continued, and but few changes have been made in the editorial staff. Among the new names are those of Drs. Griffith and Gittings, in pediatrics; Drs. Pyle and Brown in ophthalmology, and Drs. Marshall and Rhein in legal medicine. A special endeavor has been made this year, which will be continued in the future, to place at the head of each chapter a summary of the more noteworthy advances and discoveries made during the year. These should prove of use to the reader in fixing the attention on the special trends of progress in such a vast mass of literature as appears each year in every branch of medical science. The book is well printed, illustrated and indexed, and contains the following departments. General surgery, by Da Costa and Gibbon; obstetrics, by Hirst and Dorland; gynecology, by Baldy and Dorland; orthopedic surgery, by Gibney and Watermann; ophthalmology, by Pyle and Brown; diseases of the nose, throat and ear, by Kyle and Fetterolf; anatomy, by Hamann. In each of these chapters, all important American and foreign contributions are completely abstracted and give to the Year-Book the character of an excellent work of reference of what has been published during the past twelve months.

Bericht über 137 Gallensteinlaparotomien aus dem letzten Jahre, etc. By Prof. Hans Kehr. J. F. Lehmann, München.

During the past year, Kehr examined 300 patients afflicted with gall-stones, among which he operated upon 137. The latter are reported in the above work, which also contains a résumé of the non-operative cases. Kehr prefers the oxygen-chloroform anesthesia, insists on the strictest asepsis and always washes out the stomach before operation. His total mortality was 16.5 per cent., this including the cases where other operations were also done. Among 68 straight gall-stone cases, the mortality was only 3 per cent. Kehr believes that every case of gall-stones should be operated upon, as a cure results in 97 per cent. of the cases, whereas medical treatment is followed by cure in only 72 per cent. As a matter of fact, however, he only recommends operation when the history or the physical examination points to an empyema, a hydrops, or a chronic closure of the ducts. Otherwise he is guided by the frequency and severity of the colicky attacks, and also by the social status of the patient. In about two-thirds of the cases which consult him, he does not operate. Kehr does not believe that any spontaneous cures result from medical treatment alone.

ORIGINAL ARTICLES.

COMPARATIVE PROGRESS OF MEDICINE AND LAW.[1]

BY HON. W. W. GOODRICH,

OF BROOKLYN, NEW YORK;

PRESIDING JUSTICE OF THE SUPREME COURT, SECOND DEPARTMENT, STATE OF NEW YORK.

HALF a century of study and practice in my profession should have given me some knowledge of the progress of the law and rendered me in a measure capable of indicating its growth. In this branch of my remarks I may hope to interest you in what very naturally is new ground to you. When I come to speak of the advance in therapeutics, I am conscious that I shall be addressing those who know intimately what I know only superficially, and here I shall claim your tolerant indulgence. Yet the thoughts and observation of the laity to either profession ought never to be without interest and benefit to the other. It is not my purpose to decide which profession has made greater progress, but rather to set the facts before you and leave the matter to your own decision.

It would be very difficult to assert the comparative ages of the two professions. Each stretches back to the time when history began to be written. But the law has at once the advantage and the disadvantage of an inspired record. The Decalogue, announced amid the thunders of Mount Sinai has maintained its authority in all succeeding ages. The Sermon on the Mount and the other sayings of Christ were distinct progress in law, introducing more elastic rules of human conduct. But it will be seen that the Decalogue and the Sermon set a hard and high standard of law, and it is difficult to better them or to do little else than apply them to our modern life. Yet no branch of science is perfect when it has become stationary and has ceased to adapt itself to the changing conditions of humanity. Law being the statement of the relations of man to man, and of man to the State, must be judged as to its progress by the progress of humanity.

It may perhaps be said that there was never a more complete digest of law than the famous Pandects of Justinian. It will interest you to know that they were published A.D. 533, in fifty volumes, embracing all departments of law. They were the work of a body of the most learned lawyers and publicists of that age, convened by the Emperor Justinian, and consequently bear his name. While adequate to that day and still authoritative upon many subjects, many of their doctrines have become inapplicable and obsolete by the march of civilization.

To illustrate: Compare the hundred-ton shallops in which Columbus made his voyage of discovery, or the Mayflower of 180 tons burden with the modern trans-Atlantic liner of 20,000 tons. It is easily seen that the law applicable to these little vessels becomes inadequate to the requirements of the greater. Remember that it was only in 1806 that Fulton sent his first steamboat up the Hudson River and only in 1819 that the first steamship crossed the Atlantic. It is amusing to remember that in heavy storms the paddle wheels were folded in upon the deck.

Again, at the time of the American revolution the entire passenger and express business between New York and Boston was transacted by two stages and eleven horses. The first railroad locomotive in America was used in 1829. Now the transportation companies own one-seventh of the entire real and personal property in the United States.

Telegraphy was only invented by Prof. Morse in 1846. It was followed by telephony and wireless telegraphy. These instruments and methods, and the introduction of machinery in manufactures and transportation, with the resulting danger to the life and safety of the individual have changed commercial conditions, and required either entirely new rules of law, or the extension and application of old rules to the new conditions, and it is chiefly along these lines that progress has been made in the legal profession.

But even here it may be said that it is not in legal principles but in their application that the real progress of the law becomes apparent. And here the improvement in the character of courts and judges and lawyers becomes significant. It is only necessary to contrast the infamous Lord Jeffreys, murdering men under judicial forms at the order of King James, or Lord Chancellor Bacon accepting bribes at the hands of suitors and justifying the practice on the claim that it had not influenced his judgment, with such modern judges as Mansfield, Marshall, Jay, Kent and Story.

The lawyer is shackled by precedent. You may appreciate the difficulty of precedent when I tell you of the avalanche of law books which has descended upon the profession. It is computed that over 300,000 decisions are made annually in the United States, 20,000 being decisions by Appellate tribunals. Many of these decisions are inconsistent because announced in different States with differing laws. I am informed by the librarian of our law library that in a single year he purchased nearly 650 new law books, including 150 text-books and 420 reports and 77 digests of these reports, a mass of legal literature under which reason staggers. It is well-nigh impos-

1 Read before the Kings County Medical Society.

sible to keep abreast of the decisions of courts and the enactments of legislatures. Yet in these decisions the trial lawyer seeks authority for the management of his case and all results in endless litigation. Three centuries ago Bacon, Lord Chancellor of England, recommended to King James the codification of the law of England because there were 60 volumes of law reports. One digest of decisions recently published contains twice the matter of all these 60 reports!

By reason of this confusion, the State has been compelled to resort to statutory enactments, and nearly all advance has been made by that method.

History is saddened by the record of the merciless condemnation and execution of men and women for religious convictions, and this sometimes by legal authority; at other times by self-constituted church tribunals like the Spanish Inquisition, or the decrees of conquering invaders of ancient peoples. These things no longer exist.

Witchcraft was punished with death in the eighteenth century on both sides of the Atlantic, and punishment for this "crime" was only abolished in the reign of George II.

As early as the beginning of the last century in England over a hundred crimes like forgery, counterfeiting, theft, and so forth, were punishable with death. These things form a lurid background against which to paint the foreground of advance. Now, in this State, only treason and murder are punishable with death.

Included in the progress of the law is the treatment of prisoners, both in war and in peace. The moral sense is shocked by the brutality of Christian authorities to men and women, not only for crimes, but previous to the time of John Howard, for debt. It is a distinct advance that imprisonment for debt is altogether abolished. Criminals now receive merciful and reformatory treatment. Prisons are no longer pest-houses, from whose horrors death is a kindly release.

In early times persons on trial for crimes were not allowed the assistance of counsel in their defence, although the prosecution was conducted by the most learned lawyers of the day. Consider the condition of an innocent and perhaps an ignorant man, confronted with the best legal ability and the whole power of the government, and compelled to conduct his own defence. The right to employ counsel has doubtless saved many an innocent man from judicial murder.

The nineteenth century will ever be memorable in human history by reason of the abolition of serfdom in Russia, and of slavery in the United States. The former was the fruit of peace, the latter of war, but in both cases, law and justice triumphed over the wrongs of centuries.

Comparison of the legal standing of the woman of to-day with that of the woman of the middle ages speaks volumes for progress. In early times she was a serf, a chattel, a painted doll for the amusement of her lord and master. At marriage all her property passed to her husband. Now she stands by his side, his equal in legal rights, is the owner and controller of her own property, with capacity to dispose of it and to make contracts just the same as if she were unmarried.

Perhaps no greater progress has occurred than the institution of trial by jury, now so dear to the Anglo-Saxon heart. I can find no trace of this method of trial in the more ancient laws, but it was coeval with the first civil government of England and was in use in the earliest Saxon colonies, having been ascribed to the mythical Odin or Woden. It was also mentioned in the laws of King Ethelred in the eleventh century. Its use was temporarily shaken by the introduction of the Norman trial by battle, but survived that method in its general scope. Its preservation was one of the main objects of the Magna Charta, which in 1215 was wrested from King John by the English barons in arms.

It is fair to say that there have been some judicial criticisms of trial by jury, but the general consensus of opinion is that it is a distinct advance upon ancient methods.

The trial by battle was introduced into England by William the Conqueror, and it is a curious fact that such a judiciary duel was fought as late as 1638. The trial by battle was waged by champions, and not by parties to the action, because if either of the parties had been killed the action would have abated by the death—in some cases a most desirable end of unseemly controversies. Each champion made oath that he was thoroughly persuaded of the justice of his course and added: "Hear this, ye justices, that I have this day neither ate, drunk, nor have upon me neither bone, stone nor grass, nor any enchantment, sorcery or witchcraft, whereby the law of God may be abased or the law of the devil exalted, so help me God and His saints." The battle thus begun, the combatants were bound to fight, if necessary, till the stars appeared in the evening.

Corporations are of comparatively recent creation. They grew out of the principle that investments on a scale adequate to large enterprises ought to be possible in such a way that men might put at use definite portions of their property without the risk of losing all. In my opinion, it was patterned upon the ancient maritime law as to ownership in vessels, by which an owner's loss, in case of collision or other disaster, was limited to his interest in the ship.

Out of corporations have grown the momentous operations commonly known as trusts. They are still in their infancy, but new enactments are guarding against the evils which at the present time seem to threaten the interests of the commercial world.

Another evidence of progress may be found in international law. For many centuries that law has been unwritten, that is, not statutory. Like our common law it was not wholly written, but was embodied in diplomatic and judicial decisions. In the last and the present century there have been international congresses to settle matters of this nature like the International Marine Conference of 1889, upon matters relative to

navigation, the Treaty of Paris in 1856, by which, among other things, privateering (a legalized species of piracy) in time of war was abolished, and the rights of neutrals defined. The reports of these conferences were subsequently adopted by legislative action of the Great Powers, and thus made permanent statutory international law.

The Geneva Conference upon questions arising from the depredations upon our commerce of the Confederate steamers built in England during the Civil War undoubtedly prevented war between the United States and England. All mark positive advance upon ancient methods and laws, and will hereafter in large measure prevent war.

But the most notable of all advances in the law is the Constitution of the United States. Gladstone pronounced it to be "the most wonderful work ever struck off at a given time by the brain and purpose of man." John Fiske calls it "The Iliad, the Parthenon, or Fifth Symphony of Beethoven."

Under its power liberty and a great nation have become possible, permanent and inseparable. Freedom in thought, in action, in choice of rulers, in worship, so sharply contrast with feudalism and monarchy and oppression, that men of all nations are flocking to our shores to become part and parcel of the grandest nation of the ages, a nation which, in the first century of its existence has increased its population from five to seventy-five millions, and extended its territory from a narrow fringe on the Atlantic, until it has crossed the continent, and from its western shore looks across the Pacific to the land where civilization had its birth.

It is not wonderful that looking upon this marvelous growth, so conservative and English a statesman as Lord Rosebery has predicted "the sublime transference of political power and the seat of empire from the Eastern to the Western hemisphere."

I have thus in a cursory manner indicated the salient features of progress in law. Is it too much to say that the law has lifted the world to a higher plane of civil and religious liberty and has increased the sanctity of human life and happiness, and that under its benign influence the world grows better with every passing year?

Coming now to consider the advances in medicine, I am somewhat amazed at my audacity in speaking to you upon that subject. I do this with hesitation and only for the purpose of opening the discussion by yourselves. Let me premise by saying that upon this branch of my subject I am much indebted to my friend, Dr. John C. Minor, and to a study of the admirable review of Dr. William Osler, published in 1901.

While I have spoken of the great antiquity of the law, I have not lost sight of the equal antiquity of medicine. Æsculapius, reputed son of Apollo, seems to have been the mythical demigod of your science. His school in surgery has been immortalized by Homer in his Iliad, and he has been for ages regarded, not altogether without reason, as the founder of the science of medicine. Notwithstanding the fables interwoven with his history and detracting from its credibility, we can collect enough from it to be fully persuaded that his talents must have been of the very highest order, and that his knowledge must have appeared supernatural in the days of darkness and superstition in which he lived. On his death, he was elevated by his contemporaries to the dignity of a god, and temples were erected to his memory in various places, in which he was worshipped with divine honors. These temples of Æsculapius were the first medical colleges in existence. As schools of medicine, they differed in their measure of fame, in the nature of their doctrines, and in the method of their practice. It is related that he treated mental disorders with music, certainly a method not fraught with the danger of poisonous drugs. He had two sons, one of whom practised surgery and the other medicine in its general sense, and the division of the profession into surgeons and physicians apparently originated with them.

Hippocrates lived in the fifth century before Christ, and was possibly the most advanced physician of his and previous ages. It is hardly worth while to enter into the various doctrines that prevailed in the medical profession prior to his time. They were largely fanciful and childish and, as medical teaching was in a great measure absorbed by the priests of the temples, it became naturally a sort of medical philosophy in which the hallucinations of the imagination were allowed to usurp the place of observation, and the most puerile theories to supersede the cautious deductions of reason and experiment.

With the exception of Pythagoras, who was born in Samos about 600 B.C., there were none who contributed notably to the advance in medical knowledge until Hippocrates began a life devoted to studies in medicine that has made his name venerated for more than twenty centuries, and whose authority commands respect, even at the present day. Any one who studies his writings is astonished at the extent of his observation. The chief feature of his teaching was that disease is just as much a process governed by natural laws as life itself, that the process could be known by observation of symptoms which indicated the spontaneous and normal direction of recovery. Added to this was a careful attention to diet adapted to each kind of disease. He regarded medicines as of minor importance, although he mentions over 250 different drugs. His grand object was to purge medicine from the false doctrines which disgraced it, and to establish its fundamental principles on a solid and rational basis. He was a strenuous opponent of the dangerous doctrine, inculcated by the priests in almost every age, of the celestial origin of disease. He exposed the imposture of those who, masking their ignorance under the veil of piety, pretended to subdue, by charms and incantations, those complaints which they had not the skill to

encounter with the weapons of art. He taught that actual experiment, patient investigation and careful deduction were the foundations of medical science. He recognized the importance of nature in the cure of disease. He was the first to observe and describe accurately the minute circumstances of disease, the first to realize the importance of dietetics in its prevention and cure, the first to establish clear methods of diagnosis and prognosis; in a word, he was the first great clinical teacher, and for all time will be regarded as the father of rational medicine.

After the time of Hippocrates, medical progress seemed to suffer a relapse into the old ways of superstition. Much that he had taught was either forgotten or so perverted by erroneous doctrine that when Galen flourished it was full time for another revival in medicine. He lived in the second century A.D. and seems to have furnished the standard by which we may judge of progress in therapeutics. His reputation is founded not so much on original investigation as on his revivification of the doctrines and practices of Hippocrates, yet he was an acute observer, and left the impress of his genius and industry on nearly every department of medicine. He paid general attention to anatomical and physiological research and practised dissection of animals, dissection of the human body being forbidden by the religious sentiment of the age and practically illegal. His theory was that drugs contained the same elementary qualities as the body, heat, cold, moisture, dryness, etc., and that on the principle of curing by contraries, the proper drug was indicated.

It is not my intention to follow the history of medicine through the middle ages. The examples I haven given merely go to show that in ancient times about once in 500 years a medical genius was born into the world, who had something to say worth listening to and something to do worth copying. In the sixteenth century Ambrose Paré in France made his mark in surgical practice by ligating blood vessels and by improved methods of treating gunshot wounds. During that century anatomy and physiology were advanced by the studies of Servetus, Vesalius, Fallopius and Eustachius. Harvey also made his notable discovery of the circulation of the blood. The century was, in fact, the most remarkable one in the development of the more scientific departments of medicine.

I make no apology for passing over the times of Sydenham, Boorhaave, Haller, Cheyne, Huxham, Currie, Rush, Cullen and the early part of the eighteenth century, and the practice of inoculation by Jenner.

It was not, however, until the nineteenth century that the great problems of anatomy and pathology aroused scientific investigation. Bichat in 1801 placed the seat of diseases, not in the organs, but in the tissues of which they were composed. This, associated with Lainnec's art of auscultation and Avenbrugger's method of percussion, and Bright's researches on kidney diseases, resulted in differentiation of the fevers, in experimental investigations to determine the functions of the organs in health, in researches as to digestion, assimilation, circulation, respiration and excretion, with specialist investigations of all the organs, until science seemed to have explored every portion of the body. The result of these investigations was simply the building of a plane from which new efforts have been made and new results attained in every branch of therapeutics.

Dr. Osler says in his article, "Sanitary science, hygiene or preventive medicine may claim to be one of the brightest spots in the history of the nineteenth century. It is concerned with the causes of diseases quite as much as with the conditions under which these diseases prevail." Here bacteriology, as used by Pasteur, Koch, Cohn and others, was of incalculable help. Bacteria have been demonstrated to exist in rabies, fevers, leprosy, cholera, tuberculosis, pneumonia, la grippe, diphtheria, malaria, tetanus and many other diseases, and the prevalent method for preventing these diseases has come into general use.

It is well known that to a certain extent the blood and tissue cells have the power of killing germs, and this is called "general resistance." The problem has been to afford the system additional force in destroying the toxins and preventing disease where the system has partially or wholly lost its normal power of resistance to the attack of the microbes, and here the new healing art of serumtherapy finds its province in the use of antitoxins.

We come now to a period in medical science when not so much is heard of the individuals whose work advances the profession, but whose results are known to all. In old times, when a physician made a notable discovery, which was a distinct advance in medical science, his name became famous and public honors were accorded him, and all the while the vast majority of the profession remained in ignorance of the new facts and plodded along in the same old routine of practice. But to-day, when a new experiment is crowned with success or an original investigation brings a new thing in medical science to light, the whole profession is alert to seize and utilize the knowledge, while the one who has made the discovery is probably unknown to those outside of the profession. It is because I am outside of your profession that I am unable to recall the names of those who have done so much to advance the science of medicine within the last half century, but it is within my recollection that during that time the lancet has been folded up and laid on the shelf, fresh air and water have been let into the rooms of patients with fever, and the clinical thermometer and other instruments of precision have been introduced into practice.

During this period bacteriology has become known and by its application a flood of light has been thrown on the origin of disease. The study of these minute organisms has made surgery a new science and given to medicine some of its

most marvelous remedies. The use of antiseptics in surgery as a method of preventing inflammatory complications and germ contaminations belongs to that department of medicine that deals with the prevention of disease, and which in its larger sense is termed hygiene.

Doubtless the attention paid by the profession to anatomy has been the basis and reason of progress in surgery. Added to this is the discovery of anesthetics and antiseptics, by means of which surgical operations which startle the laity have become commonplace to the surgeon. The Roentgen rays, anesthetics and antiseptics have made miracles possible. A recent incident astonished the lay world. I refer to the treatment of a patient who had collapsed under an anesthetic. The attending physician quickly opened his thorax and taking the heart in his hand gently massaged it, so as to imitate its normal action and the patient's life was saved.

It may be deemed heretical in this body to say it, but it seems to us of the laity that Hahnemann rendered distinct service to medical science, not so much by his theory of *similia similibus curantur,* which was diametrically opposed to the theory of Hippocrates and Galen, as by inducing the use of smaller doses of medicine. A curious experiment was tried in the Massachusetts General Hospital in Boston. The story is told by Dr. Bellows, an allopathic physician. Three wards, exactly similar in all respects, were assigned, one to the allopathists, one to the homeopathists, and one to the eclectics. Patients (not surgical), as they came into the hospital, were assigned in strict numerical order to each ward. The result at the end of the year was that the percentage of deaths in the allopathic ward was six per cent., in the homeopathic ward four per cent., and in the eclectic ward, two per cent.

As in this connection, I may say that much has been learned from that true homeopathic physician, Doctor Mosquito, who alone of physicians, continually carries his scalpel-probe on that part of his anatomy where it is calculated to be most effective. His professional brethren have been swift to apply the knowledge of his practice in the treatment of their own patients.

Another advance is the absolute change from the old irresponsible certification of physicians to their regulation, not only by education, in the great medical colleges and the issuing of diplomas, but by the positive prohibition of the State against the practice of medicine, except by educated persons holding such degrees. The severer the tests and examination, the better for the public health and for the medical profession.

Positive progress has also been made, not only in the treatment of the insane, but in the study of the causes of insanity and idiocy. This has extended to all civilized nations, and these unfortunates are no longer regarded as unworthy of care and study.

The trained nurse is a most remarkable evidence of medical progress. We need only to compare Betsy Prig and Sairy Gamp abusing poor old Chuffey in "Martin Chuzzlewit" with the educated, informed, neat-handed, watchful young women, who make sickness comparative luxury, and to remember that symptoms and conditions are watched and reported to the physician with a faithfulness born of enthusiastic devotion to what ought to rank as a learned profession. I am always proud to remember that the first State school for the education of nurses was established in the Brooklyn Maternity, for which I drew the incorporation papers, and in which my wife was a faithful worker for many years.

In dietary matters, however, there seems to me to have been a decided lack of observation. I do not mean diet to the sick, for that receives the utmost attention—I mean attention to previous diet. I can hardly recall an instance, in my own experience, where my physician inquired of me what my previous general course of diet had been in order to acquire diagnostic knowledge of my condition and its cause.

We have learned so much, during the past fifty years, of the avoidable causes of disease that it gives rise to some natural queries. For instance, malaria and possibly yellow fever is known to arise from an infection carried by the mosquito; mosquitoes are killed by drainage or by covering the surface of their breeding places with a film of petroleum. Query, why should not the mosquito be utterly abolished and wiped off the face of the earth by a scientific application of the means at our disposal?

Again, the tubercle bacillus is recognized as the probable cause of true tuberculosis. This bacillus lives and germinates in living animal matter only. If every tuberculosis animal is either isolated or killed, why should not consumption be afterward unknown on earth?

Typhoid fever ought to be a preventable disease, requiring a proper sewage disposal that will destroy all germs, so that there would be no possibility of contamination of drinking water or food products. Would not systematic control of sewerage systems by government abolish typhoid fever?

Is it fair to compare the progress of our professions by results? Yes, in a measure, for we practice upon the knowledge at our command. The Bible declares, "By their fruits ye shall know them." The fruits of a lawyer's services to his client are gathered or lost at the end of the lawsuit. The result is concrete and apparent. But we must start with the fact that in all cases one of the opposing lawyers always loses. Hence each lawyer theoretically loses half of his cases.

Here I admit your great advantage. Your single adversary is the Grim Reaper. What is your proportion of successful contests with him? We lawyers may not hide our mistakes under any Hippocratic oath. Far be it from your servant to suggest that *you* ever make mistakes!

A lawyer and a doctor were riding past a gallows bearing its ghastly fruit in chains. The doctor said, "There hangs the victim of your legal mistakes." Presently they passed a

cemetery and the lawyer said, "There lie the victims of your medical mistakes." In both cases, however, dead men told no tales.

But we have this advantage: We advise and act upon the facts as related to us by our client. You can only diagnose, necessarily with difficulty, because partially, upon symptoms described by a sick patient's fancies. You may not see inside the body except by the imperfect X-rays. The wonder is that you accomplish so much as you do.

Sometimes, especially when I have lost an important lawsuit, I have doubted whether lawyers, except in rare instances, are of benefit to the world. But there never was doubt as to the physician. We envy you the power of ministering to humanity, of ameliorating suffering, of saving the dear lives of men and women and little children. Verily the good physician is God's vicegerent on earth.

HIGH-FREQUENCY CURRENTS; THEIR PHYSIOLOGICAL ACTION AND METHODS OF APPLICATION.[1]

BY A. D. MABIE, M.D.,
OF PEEKSKILL, N. Y.;
CONSULTING ELECTROTHERAPEUTIST, JAMAICA HOSPITAL, JAMAICA, L. I.

For many years, thanks to the researches of D'Arsonval, Oudin, Doumer, and others, high frequency currents have been employed in Europe in electrotherapy. The field of their application has constantly widened, but it is only within a very short time that their value has been recognized in this country.

The question is very frequently asked, what are high-frequency currents, and it may be said that they are the extremely rapid isochronous oscillations which are obtained when a condenser charged to a high potential is discharged into a conductor having a certain self-induction and feeble resistance. They are in reality currents of high potential as well as high frequency. High frequency enables us to obtain extremely high tension, the latter being necessary for the experiments investing high frequency properties in light. The theories as to the nature of light have been modified in late years, and the resulting experiments have founded the electromagnetic theory; the identification of electric and light phenomena. According to these theories, the phenomena are due to a periodic movement of the ether. The two phenomena present striking analogies, and one is obliged to admit that electric and light vibration differ only in frequency and wave length.

From a physical standpoint, high frequency currents are distinguished by three properties which are due to the great frequency and the high tension put in action. These are as follows:

First.—Very intense phenomena of induction. The electromotive force induced in a conductor by a neighboring conductor is in proportion to the product of the current by the frequency. Therefore, the electromotive force induced either by the self or mutual induction in a single spire is very great, and in a large solenoid will by the mutual induction light an eight-volt one ampere lamp. Auto-conduction is an application of this principle, one utilizing in this case the currents induced in the circuit formed by the mass in the human body, or certain parts more conductive.

Second.—Since the least capacity enters into play, high frequency currents circulate as well in open as closed circuits, so that contact with a single pole suffices to furnish the current. However feeble the capacity may be, the charge and discharge is repeated hundreds of thousands of times per second under a high tension, and it is this which explains the unipolar currents and the sparks which are obtained when a single spire of the solenoid is touched. In this case the body constitutes an insulated circuit which, at each oscillation, is charged with an almost constant quantity, since it is at a certain distance from the solenoid. The opposite charge must be found on the poles of the solenoid which are of a different potential.

The illumination of the lamp may be explained by the effects of condensation; the glass being the dielectric, the vacuum and the filament forming one electrode, the moist skin the other.

Third, Phenomena of Resonance.—This will be described under methods of raising tension.

While Hertz, Tesla, Thomson, and others studied these currents from the standpoint of their industrial utilization, D'Arsonval made his researches from a purely physiological point of view. His experiments extended over a period of several years, and have established the fact that high-frequency currents are valuable electrotherapeutic adjuncts.

SOURCE OF HIGH FREQUENCY CURRENT.

These currents are obtained in many ways, and many ingenious devices have been employed for furnishing them. A coil or a static machine may be employed as the exciting apparatus. D'Arsonval employed a low frequency coil provided with condensers, the outer coating of which was connected to a solenoid of coarse wire.

The phenomena of the generation of high-frequency currents from whatever exciting apparatus employed, may be explained as follows: At each rupture of the primary circuit there is produced an induced electromotive force. This electromotive force charges the condensers to which is united the solenoid; the solenoid itself being traversed by the current of charge. In proportion as the charge is effectuated, the difference of potential at the discharge rods of the condenser increases, and when it reaches the limit corresponded to the separation of the balls of the discharge rod, perhaps many thousands of volts, the spark breaks. This spark forms a bridge of feeble resistance by which the charge of the condensers is quickened. The oscillating discharge leaps from one ball to the other, during which the solenoid attached to the external armature of the con-

1 Received for publication April 9, 1904.

denser is traversed by an alternating high-frequency current. The interval of the micrometer is then traversed at the time by a spark of unique direction due to the coil, and by the oscillation of the condenser charge, while the solenoid is only traversed by the condenser discharge and the oscillation of the discharge. The first being relatively slow, cannot give in a conductor resistance of any appreciable tension, so that the only difference of potential which can exist there are those due to the oscillation, which are inoffensive.

PHYSIOLOGICAL PROPERTIES.

The physiological properties of high-frequency currents may be considered under four heads: Their action upon the nervous system, the circulation, the respiration, and the urine.

Action Upon the Nervous System.—An essential property which distinguishes high-frequency currents from all other forms of electrical energy, even when currents of formidable intensity are employed, is that it exercises no action either upon the general sensibility or muscular contractility, there being experienced only a slight sensation of heat at the point of entry and departure.

When sparks are allowed to fall upon a motor point, or upon the skin, there is an action upon muscular contractility which might lead to conclusions that the nerves were impressible to the current. This action upon the sensibility and the pain is caused by the very great density of current and the shock of the spark at the point of penetration. The area treated being very small, the passage of the current develops considerable heat. Small electrodes in immediate contact with skin may set up a sensation of heat which may be disagreeable, whereas large electrodes diminish the density and diffuse the heat. The muscular contractility caused by the spark is due to the discontinuity of the discharge, the brisk variation of the electromotive force corresponding to the establishment and breaking of the spark.

These facts, then, permit this fault of action to be attributed to the extreme elevation of the frequency of the current, our nerves being incapable of responding to excitations so rapid. There is therefore absence of sensory or motor excitation, inhibitory effects, and effects upon the vasomotor system as shown by fall of arterial pressure. The analgesic action in certain cases can be carried so far as to obtain complete local anesthesia. This does not penetrate deeply, and persists from a few minutes to a quarter of an hour. Oudin has shown that the spasmodic anemia produced at the point struck by the spark from the resonator extends for two centimeters succeeded by a true local trophic trouble. There is a slightly painful sensation at the beginning of the operation, which soon becomes absolutely painless.

Action Upon the Circulation: Direct Application, Condensation—There is a vascularization of the skin which is covered with sweat consequent to the action upon the vasomotors. Variations in resistance of the capillaries necessarily excite modification of the arterial pressure. This is diminished if the small vessels are dilated, increased if they are contracted.

When the spark of the resonator is directed upon the skin, one sees about the point touched from 20 to 30 cm. circumference a diffused redness extending to large areas, persisting 20 to 30 minutes with papillary erection, followed by anemia due to a very energetic vasoconstriction. After some instances an erythematous tint may remain many hours, or in some patients many days. One obtains by this process a greater increase of the arterial pressure than that which one establishes after auto-conduction. Oudin has by means of the sphygmomanometer of Laulaine shown that when the effluve of the resonator touches some point of the body there is instantly produced in the capillaries of the hand of the subject a vasomotor spasm characterized by a notable lowering of the general curve. He has sometimes established in the same time a diminution of the amplitude to the pulsations, sometimes almost complete suppression. It presents, nevertheless, before returning to its normal form and amplitude, alternative periods of lowering and elevation which seems at times to produce a series of vasocontractions and vasodilatations less and less accentuated.

Action Upon the Respiration.—Under the influence of the high frequency currents, the number and amplitude of the movements of the respiration increase, and D'Arsonval has shown that the volume of oxygen absorbed and the carbonic acid emitted increases considerably. The examination of the blood made by Tripet before, during, and after treatment at the Apostoli Clinic upon patients affected with different affections, showed that in 37 cases the high-frequency currents increased the activity of the reduction of the oxyhemoglobin in patients with lowered nutrition. In ten cases where before treatment the activity of reduction was exaggerated, the current caused a lowering, approaching the normal. In only six cases the organic loss continued to lower in spite of treatment.

Action Upon the Urine.—By the direct application D'Arsonval has shown that high-frequency currents regulate diuresis, increasing the elimination of extractives, notably urea and also increasing the toxins.

Apostoli and Berlioz made 761 chemical analyses upon 281 patients, and showed that high-frequency currents caused amelioration of diuresis and more easy elimination of excreta, a greater suractivity of combustion, with a tendency of the relation of uric acid and urea to approach the normal average, 1.40. Berlioz noticed with condensation that the nutritive processes appeared more active, that urea, uric acid, phosphoric acid and chlorides were notably increased. Real and Rienzi demonstrated that this treatment diminishes about one-half the neutral or not completely oxidized sulphur contained in the urine. They attribute, moreover, a manifest action upon nuclein shown by the simultaneous increase of uric and phosphoric acid.

Methods of Application—High-frequency currents are applied under different modalities, one utilizing, as the case may be, either direct applications, local applications, auto-conduction, condensation, or resonator applications.

Direct Applications—It is known that high-frequency currents circulate in a solenoid, and a patient being in shunt by being attached to the two points will be traversed by the current. As a consequence of self-induction the solenoid offers a greater resistance, and the current, therefore, passes by preference through the shunt circuit of which the patient forms a part.

In the direct stable application, the patient is connected to the two poles of the solenoid by means of conducting cords attached to metal plates of different dimensions, or covered with moistened felt or chamois and applied directly to the skin. The metal plates should be of such a thickness as to be easily molded to the surface. Care should be taken when applying them to the diseased area to see that there are no folds of the covering, or air spaces between the metal and the skin, for the reason that if this is overlooked ulcers or burns may occur.

Labile applications are made by having one fixed attachment, the other end of the solenoid being attached to an insulated movable electrode.

Local Applications—In local applications a point, wire brush, or metal ball such as are commonly employed for static treatment is attached to one pole of the solenoid by means of a flexible insulated cord. The other extremity can be connected with the patient by means of a large tin plate, attached to the earth, or left free. If one pole of the solenoid is attached to the earth, a greater potential is created at the opposite pole and a larger effluve is obtained.

REACTION PROVOKED BY DIRECT AND LOCAL APPLICATIONS.

The immediate impression experienced by the patient is almost nil, there being only a light sensation of heat at the level of the electrode, or in its neighborhood. On the contrary, if the application is defective, the patient can experience a sensation of burning and slight erythemia. Some patients cannot support the temperature to which a carbon tampon is carried covered with soft wool and ulcerations may occur; others experience a sharp pain when one throws the current into circuit, which pain must be related to lesions of the skin subjacent to the electrode, since it is sufficient to displace this in order to cause the cessation of all disagreeable sensations. There is also noticed in some cases an analgesic action, vasomotor resolution. Lassitude is sometimes observed following the seance persisting for some hours or localized for five to ten minutes.

ELECTRODES.

Different electrodes are used for local applications. Those most commonly employed are metallic brush, point, multiple point, ball, or some form of glass vacuum tubes exhausted to a Geissler or Hittorf vacuum.

The metallic brush should be composed of very fine flexible wire, and is employed in chronic affections of slow progress without any inflammatory reactions. Where effluvation of a limited area is desired, a metal point should be employed. This should have a very sharp pencil point. Where a diffuse application of the effluve is desired, the multiple point may be employed.

For the treatment of sensitive surfaces, as the face or mucosa, or any region where inflammatory reaction has increased the sensibility, glass electrodes should be used. Many types of glass vacuum electrodes have been devised for this purpose. The type I prefer is that provided with a wire running to within one-half an inch of the distal extremity of the tube, and exhausted to a Hittorf vacuum. These may be termed a condenser which discharges itself at each oscillation by a shower of fine, small, and violaceous sparks. These sparks are easily supported by the most inflamed skin or delicate mucosa. Different types of these electrodes are shown in Figs. 1 and 2.

If one approaches the skin with an electrode attached to one pole of the solenoid without completing the circuit by a contact with the other pole, sparks occur which provoke a revulsion much more lively as the action is prolonged. This revulsion is followed at first by a light localized redness very quickly diffused and extending to a surface sensibly greater than that attacked by the spark. The redness persists from twenty-five to thirty minutes after electrization. About the point touched a sort of anemia of the skin takes place, which becomes a chalky white with erection of the papillæ. This condition persists for one or two minutes, according to the subject, then the papillary erection little by little disappears, and the spasmodic anemia of the beginning is succeeded by quite a strong erythematous tint which sometimes persists for several hours. In certain subjects with particularly sensitive skin one can even notice the next day the presence of the erythemia. Oudin (*Annales d'Electrobiologie,* 1898) declares that one can even see "if one prolongs the local action after several hours a phlyctenula at the point touched."

When the opposite extremity of the solenoid is attached to the earth and the electrode is in connection with the patient, the effects are a little less accentuated. It is not easy to utilize the effluve exclusively, because, being almost the same length as the spark, but a slight displacement of the electrode is necessary in order to obtain a spark.

Direct sparks may be administered locally by attaching an electrode to one of the extremities of the solenoid of the exciting apparatus. If the other extremity of the solenoid is grounded or attached to the patient, the sparks are more powerful. This method of application is very little employed on account of the painful sensation arising from the spark. This can be lessened to a degree by replacing the ball or point with a metallic brush, thus diffusing the action to a larger surface. The current, however, is still painful to a

healthy skin and intolerable to a diseased one. The boundary line of the spark and effluve is very short with this application as a very slight difference in the distance of the electrode from the area under treatment causes the spark to jump. For this reason this method of application is very little used. To overcome this one may use either a Tesla coil or the properties of resonance, the last being the means most generally employed. The local applications are thus easily controlled and well tolerated.

The principle of resonance is founded upon the fact that two sonorous bodies may be so constructed as to vibrate in unison yielding the same tone. When this is accomplished it is only necessary to vibrate one to cause the other to enter into vibration. This phenomena is also present in electric vibrations, and Hertz being aware of this fact constructed an apparatus of feeble self-induction and capacity under the name of resonator. This was so constructed that the period of the resonator furnishing sparks coincided with the period of the vibration of the exciting apparatus, and was itself the seat of oscillations.

The diameter of the spires of wires constituting the resonator has no great importance from the standpoint of the production of resonance, but it has a considerable influence upon the physical property of the effluve and spark. If one employs a fine wire one obtains a spark, weak, long, and sinuous, slightly painful, the effluve being also much less nourishing. With a wire of greater diameter the effluve and spark gain in power, these being in relation much more with the total capacity of the exciting apparatus than with its self-induction. It is for this reason that the capacity of the Leyden jars must be feeble.

The maximum speed of a resonator depends upon the establishment of a perfect pitch between it and the solenoid of the producing apparatus. This result is obtained by varying the number of spires in the circuit, thus modifying the self-induction and the capacity. Having established the pitch of the solenoid and resonator, if one changes the relation of the self-inductor or the capacity, they do not vibrate in unison, and the effluve or sparks become smaller and smaller and finally disappear.

Oudin in 1892 devised the first resonator employed in electrotherapeutics, consisting of a solenoid of copper wire, which by a given relation between the number of its turns and the number of turns of the primary solenoid of the exciting apparatus gave a bouquet of effluve or sparks.

His new model is an inducto-resonator, and as consequence of superposition of the primary solenoid upon the prolongation of the resonator, it adds to the phenomena of resonance that of induction.

A new inducto-resonator manufactured by Van Houten & Tenbroeck Co. has proven very satisfactory in my hands. This is so constructed that direct, local, or resonator applications may be made. The effluve is very large, varying from one to four inches. The current strength is regulated by the distance of the discharge rods, attachment to resonator or coil posts or grounding. The yield is superior to that of any other apparatus, and affords a more extended and delicate production of its effects. This is shown in Fig. 3.

The current furnished by the resonator, or the high tension coil, whatever it may be, can in fact be applied to the patient in many ways. The application may be continuous or discontinuous. It is continuous if one employs a copper electrode in immediate contact with the skin or the region to electrolize. It is discontinuous if one employs a wire brush held at a distance, or better, a glass electrode. A brush of metallic wires promenaded upon the skin presents, however, less discontinuity than in the case where the same broom is held at a distance. This distinction has its importance because the reaction of the patient produced by these different applications is different. Local application can moreover be monopolar or bipolar.

Certain apparatus permit of submitting the patient to the effluve or the sparks furnished simultaneously by the two poles of the resonator or the high tension coils. In this case the two poles are active, if one can express it thus, but one can still realize a bipolar application in attaching the patient by an indifferent electrode to the extremity of the solenoid opposite to the pole connected with the resonator. Finally, one can attach one extremity of the solenoid of high frequency to the earth, or better, not connected either with the patient or the earth. In discontinuous applications the effects are varied by modifying the distance of the electrode to the region submitted to treatment. If one wishes to increase the action of the effluve through the body in a determinate direction, one can place upon the region opposite to that where it is applied an indifferent electrode which one uses in the bipolar applications.

The same rssults may be obtained in different conditions by means of a process indicated by Oudin. The lines of force of the oscillations in the body of a patient attached to the resonator can, in fact, be directed in a certain measure towards a determinate region by approaching to the point upon which one wishes to act more particularly a capacity, such as the hand, for example, or a sphere. Break the sparks between the capacity and the body, as the sparks are longer as the density of the current is greater, that is the surface of contact is much smaller. Curiously these sparks are more disagreeable when the patient is struck by the effluve than when he is in direct contact with the resonator.

Glass electrodes diminish and even suppress painful impressions. The anemia of the skin, the erection of the papillæ, and the redness which appears successively in the course and as a consequence of the application, depend upon the intensity of the treatment. The revulsion can be intense and go as far as a vesication if the sparks are particularly powerful or if they are applied for a very long time and very often repeated in the same place. After the seance the patient gener-

ally experiences beside a sensation of heat an impression of local well being. The skin is soft and moist. Often, either during or after the application, one sees small drops of sweat covering the integument.

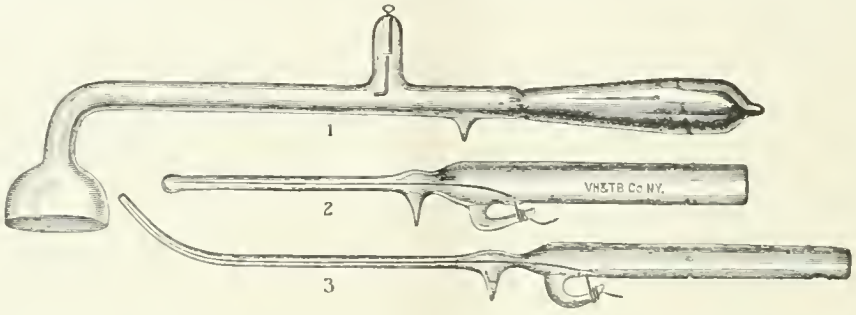
Oudin gives the following hypothesis as to the action of the effluve of resonance. He believes that the skin acts as a dielectric and is traversed with the greatest facility by the effluve which charges the capacity formed by the adjacent tissue to the effluve; it acts as a volumetric capacity which will be submitted to the electric oscillations, spreading itself in all its mass, slowly decreasing, and not as the internal armature of a condenser of which the epidermis may be the dielectric. The alternate waves appear from their point of entry in the body to diffuse in the mass of the organism as the stretch from the surface of still water, parting from the point which has been struck by a stone, or more exactly as sonorous waves expand in the air from a vibrating cord. (*Annales d'Electrobiologie*, 1898.)

Reaction Provoked by Local Applications Affected by Means Which Raise the Tension.—The reaction of the patient varies equally with different conditions. Heat is often produced by the high-frequency currents, as may be noticed when an electrode is taken in the hand and one is struck by the sensation of heat rapidly developed at the points of contact. Oudin has demonstrated that the quantity of energy which circulates in a conductor is relatively considerable and quite superior to that of static machines. (*Annales d'Electrobiologie*, Aug., 1899.) The sensation of heat is specially appreciable when one applies a metallic brush to the skin or when one draws some sparks.

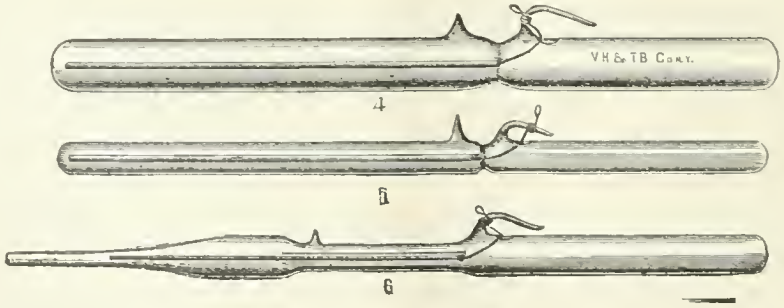
From the standpoint of their immediate action, the effluve and the spark differ much. The effluve provokes only a slight prickling, and is in general well borne. The sparks are more or less painful, according to the condition of their application. They are supported in a variable manner according to the susceptibility of the patient.

INTENSITY, NUMBER AND DURATION OF SEANCES.

The intensity of the current is varied by changing the number of the spires of the solenoid introduced into the circuit. One can modify the point of contact of one of the rheopores upon the solenoid, the other remaining fixed at the same point. Thus one approaches or removes the two doses of the current more or less; but this process has the inconvenience of prolonging the uncertainty necessary to obtain the desired intensity.



It is hardly possible to indicate the necessary intensity to employ. The physician must in each case proceed with caution. Watch with care the first seances of the treatment, and the reaction of the patient will quickly inform as to the advisability of a diminution or an increase of intensity. One cannot fix the rules relative to the duration of seances or their repetition. In general, prolong the application ten minutes and administer three times a week. In certain cases, fifteen-minute applications or daily repetition have appeared to accelerate the amelioration. The conditions must vary with the nature of the disease and the tolerance of the patient.



Auto-conduction is distinguished from all other methods of electrolization by the absence of all contact establishing a communication between the current and the patient. The subject is placed in an oscillating magnetic field engendered in the large solenoid without any communication with it. The solenoid, being traversed by the high-frequency currents, induces extremely powerful currents, not only on the surface of the body, but as far as the intima of the tissues. A horizontal or

vertical solenoid may be employed of a size which will enable the patient to stand up or lie down.

Apostoli employs two methods: a solenoid without contact or a solenoid in which the patient is in contact by grasping one of the poles in this arrangement. The patient is in monopolar shunt, while at the same time he is submitted to auto-conduction.

In the beginning of the seance, or immediately after, some patients will complain of headache, with inability to read, vertigo, and nausea, accompanied by immediate and rapid malaise. After a few hours this reaction may be followed by fatigue and extreme lassitude, with a return of old pain which appeared to have been suppressed. According to Apostoli, this reaction, if existing, attains its maximum intensity in the solenoid without contact, being less for the cage with contact.

The hysterical anesthetic presents these reactions most particularly. In the majority of cases, however, this mode of application rarely provokes so accentuated reactions. In senile rheumatics, certain diabetic, the anemic or chloro-anemic, the reaction may run from a simple sensation of lassitude to an impression of overwork.

Denoyes found that no sensation other than a slight prickling or feeling of heat either during or after the treatment was experienced in some cases. At the end of the treatment some complained of the above symptoms to a mild degree. Apostoli studied this phenomena very carefully, and concluded that where such reaction appeared it constitutes a contraindication for the use of auto-conduction.

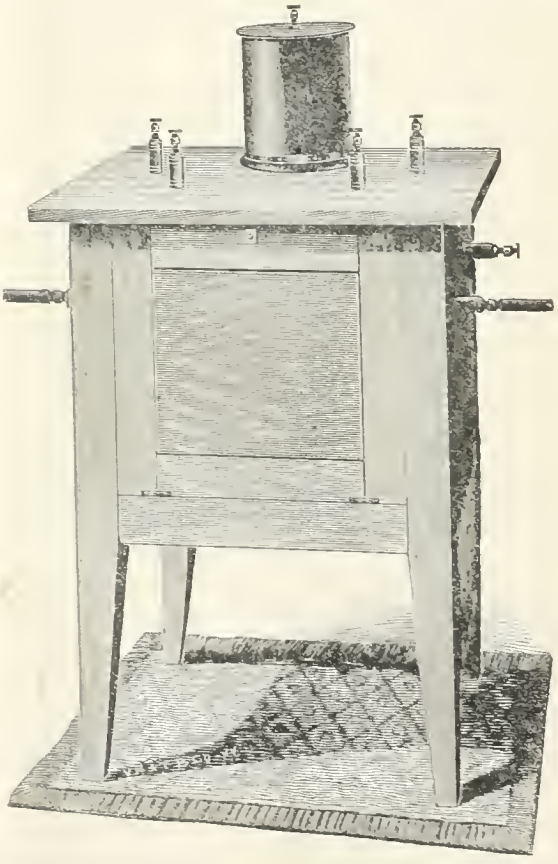
These reactions may be provoked in the beginning, gradually weakening, and finally disappearing as treatment continues. In others it may not appear till after the second or third seance, especially as they are prolonged. Finally a brisk increase of the regular durations of seances causes appearance of troubles which up to that time may never have been manifest.

It would appear from these different reactions that some precautions should be taken in the application of auto-conduction. It is always well to begin with short seances, two or three minutes, progressively increased. This obviates disagreeable and discouraging first impressions.

CONDENSATION.

This method consists in placing the patient so that he constitutes one of the armatures of a condensor. Upon a couch or sofa is placed a sheet of lead, tin, or zinc, attached to one of the extremities of the solenoid. Over this is laid a mattress of insulating material upon which the patient reclines. Fixed in movable contacts attached to the other pole of the solenoid in an intermediate point are grasped by the patient. The whole of the system constitutes a condensor. The patient represents one of the two armatures, the metallic plate by the other, the mattress forming the dielectric. By this system a current of as much as 300 milliamperes can be made to pass through the patient. At each oscillation, in fact, the condensor is charged and discharged.

We know that high-frequency currents circulate perfectly in open circuits since the least capacity enters in play. However feeble may be the capacity, the charge and discharge is repeated hundreds of times per second under a raised potential constituting a notably mean current. One also can observe the passage of a current or the production of sparks when one approaches or touches a single point of the solenoid. In this case the body constitutes an insulated surface which is charged at each oscillation of an almost constant quantity, and which is at a certain distance from



the solenoid. The corresponding charge of a contrary sign should be found upon the parts of the spiral which are at this moment of a different potential.

Reaction Provoked by the Method.—The patient submitted to the application generally experiences only slight trembling in the hands at the immediate point of contact with the current. This sensation, according to Apostoli, is always well borne and must never go so far as to cause pain. It is easy to establish the fact, however, that the subject placed upon the *lit condensateur* is really electricized. If one lightly touches the skin with the finger ends, he can perceive small painless sparks. If one approaches the hand to the patient's head without breaking the sparks, there is often experienced a sensation difficult to explain,

and which can be spoken of as a heavy head. Apostoli stated that intolerance is manifested for most patients to a lesser degree under condensation than under the large solenoid. Denoyes finds, however, in senile rheumatics, certain neurasthenics, vertin diabetics, anemics, and chloroanemics, that the *lit condensateur* is more fatiguing than the cage. The intensity of the current to which the patient is submitted varies with the regulation of the producing apparatus.

It is not possible in so short an article to furnish a formula of the indications of high-frequency currents because of the diversity of their methods of use and the extent of their field of application. It can be said, in conclusion, however, that they have been employed and given excellent results in diseases due to lowered nutrition, affections respiratory tract, affections alimentary canal particularly, constipation, hemorrhoids, and anal fissure, neurasthenia and neuritis, articular affections of different origin and in great number of dermatoses.

The only contraindications for high-frequency currents is any valvular disease of the heart, or those suffering from hysteria.

ARTHRITIS DEFORMANS AND ITS TREATMENT.[1]

BY LOUIS KOLIPINSKI, M.D.,
OF WASHINGTON, D. C

The arthritis deformans of Virchow (1869), which possesses twenty-five or more synonyms, was first correctly recognized as a particular disease by Landré Beauvais in the year 1800. It is a chronic degeneration of the joint cavities, and has a special and distinct symptomatology which for centuries was confounded with gout, with rheumatism, and other infectious diseases of the articular apparatus.

Its etiology is as yet undiscovered. Its pathology consists in mucoid degeneration and disappearance of the central part of the cartilage; erosion and eburnation of the exposed bone; hypertrophy and fatty degeneration of the synovial membrane; newperipheral cartilage growth, and later ossification thereof.[2] A. E. Garrod says there is a fluid effusion, others, that the parts are dry. With these profound changes, fibrous adhesions do not occur, and bony ankylosis only in the disease of the vertebral column. There is secondary atrophy of the voluntary muscles and an anemia, blood abnormal in hemoglobin and red blood corpuscles.

The disease may seize upon the joints of the upper and lower extremities, with or without involvement of the vertebral column and of the temporomaxillary articulation. Its invasion is centripetal and symmetrical (this is the polyarticular or multiple form).

In both sexes and at all ages except infancy, it is five times more common in women than in men. Most cases develop between forty and fifty years, either as an acute inflammatory outburst or insidiously with pain and stiffness most felt at night and in the morning. It is the most frequent acute or chronic disease of the joint system, and much oftener encountered than articular rheumatism, gout and the several joint infections combined. Multiple arthritis deformans is so common in middle-aged and elderly females that the theory of it being a senile change is at least plausible.

The disease has acute exacerbations simulating mild articular rheumatism with slight febrile temperature. There is constant complaint of pain, articular, muscular and neuralgic; of stiffness of motility, tenderness of the joints. The swollen joints stand out more prominently, because of the wasted muscles.

This fixation of the joints may, by natural progression be temporary or permanent, limited to the knees or vertebral column, or so general that the helpless victim, with mummy-like rigidity, cannot even use the jaw in mastication. There is no spontaneous recovery, and the afflicted live for years. The termination of the disease in its natural course is rude and truly deforming.

The monarticular or senile form affects the vertebral column most disastrously as spondylitis deformans, more common in men; malum coxæ senile, in both sexes. Occasionally it also affects a shoulder, elbow or knee. That these varieties all belong to the same affection as the polyarticular is proven by the fact that all have symptoms present in common, which must always be considered for correct diagnosis, to wit: (1) Heberden's nodes of the phalangeal joints of the fingers; (2) numbness and tingling of the hands and forearms; (3) crepitation of the knee-joints, especially of the left side. This is produced by pressure on the patella with rapid flexion and extension of the leg; (4) a pulse of 100 or more beats per minute. Heberden's nodes and knee crepitus are found in every case of arthritis deformans.

The indications for treatment of this extraordinary malady in our present imperfect knowledge of the same is comprised in the following summary: (1) Relief from pain; (2) correct the stiffness and rigidity of the affected joints and muscular contractures; (3) increase the muscular strength; (4) cure the anemia; (5) increase, where necessary, the body weight; (6) symptomatically regulate or slow the pulse.

To fulfil these indications three agencies are necessary, and so indispensable is each one that no two alone will suffice to achieve good results. They are (1) for pain, anemia, the rapid pulse and malnutrition—arsenic; (2) for stiffness, contracture and muscular atrophy: voluntary exercise; and (3) for weakness, anemia, loss of weight and the pain, greater nutrition brought about by increasing and selecting the food supply.

Arsenic was recommended by Bardsley in 1839, and has been approved by Fuller and Balfour, by Strümpell and others.

1 Read at the Annual Meeting of the American Therapeutic Society, New York City, June 4, 1904.

2 Archibald E. Garrod. Arthritis Deformans Twentieth Century Practice, Vol. ii. Alfred Pribram. Nothnagel; Specielle Pathologie und Therapie, Band 7, 5. Theil.

Success with arsenic depends on the method, manner and length of time. It should be used a year or more. It must be so administered that mild arsenical poisoning does not occur, namely, edema, headache, nausea, vomiting and diarrhea. In using arsenic, arthritis deformans may be divided into the mild form, the common polyarticular one, where the chief symptoms are stiffness and pain of no great intensity, and the severe or monarticular variety: spondylitis deformans, malum coxæ senile and all cases where the patient is helpless and bedridden.

For the mild type, one or two drops of the liquor potassii arsenitis U.S.P. after meals thrice a day may be used for a very long time, with very satisfactory results. The pains, whether muscular, articular or neuralgic, disappear after a month or two. When this has been achieved, the treatment must continue with unremitting regularity.

Arsenite of zinc may be used instead of Fowler's solution. The dose is one-twelfth of a grain in the form of a pill, repeated twice a day. In the severe forms the arsenic is used in hypodermic injection, as by the mouth the effects are too slow and uncertain. The risk in loss of time is too great a venture. An injection should be made in the lateral gluteal region every third or fifth day. In 60 minims of boiled water are dissolved three-eighths of a grain of sodium arsenite and 1½ grains of sodium of chloride. This solution is painless, unirritating and never causes abscess. As in the former form of medication, these injections should be continued for a year.

Mechanical treatment of the active kind is best in all cases. The patient must be encouraged to help himself. Passive exercise is demoralizing because it produces apathy and engenders an expectation of improvement that does not come.

The principle to be impressed upon the minds of the afflicted is that rest for a limb is harmful. Rest in bed aggravates the disease by favoring immobility of the joints. Daily exercise is beneficial, though productive for a time of pain and discomfort. Daily walks and rides, household and other manual occupations are necessary in the mild forms. For the severe and advanced stages, the use of dumb-bells and calisthenic exercises to give strength and vigor to the upper extremities; daily locomotion with regulated and increasing distances for the lower limbs. Where there is much impairment of function in knee or hip, this exercise must for a long time depend on the aid of crutches or stout walking cane.

A valuable means of restoring the power of locomotion when abolished through partial anchylosis and muscular atrophy is the daily use of the pedals of an ordinary bicycle secured to the top of a short upright bar or post. It rests upon an appropriate stand or pedestal. The patient seated upon a chair or astride a trestle, can, by making the pedals revolve with his feet do much to accomplish improvements and cure. In many cases the radius of excursion in the patient's limbs is so restricted that in the beginning it will be necessary to secure the pedals nearer to the central axis than is found in the contrivance employed. The shafts therefore are perforated with holes at regular intervals into which the pedals when screwed make the rotations larger or smaller. At first also it may be necessary to secure the subject's feet with straps to prevent them from slipping, or else to hold them by hand until sufficient voluntary control of motion is acquired. By keeping a record of the number of revolutions to the point of muscular exhaustion the very great benefit derived from this exercise will be made apparent to the victim of the disease. Starting with twenty-five or fifty small and painful turns a day, in a month or so two thousand easy rotations are made. In fact, the speed and strength reached may surpass the powers possessed by one in health.

The dietetic treatment is of great importance. Improvement cannot occur without it. There is in arthritis deformans, loss of weight, muscular atrophy and anemia. To counteract these, food consumption is the best of means.

The diet should be varied, liberal and mixed, consisting in the daily use of meats, fowl, game, fish, eggs and all varieties of vegetable food. The patient's appetite must be tempted and whetted by gastronomic and culinary art. In addition to three regular meals a day, the consumption of three or four pints of milk at other hours, and at night, is the best of means for improving strength and weight.

Dessert is forbidden, and fruit particularly does harm, with the solitary exception of the watermelon. Alcoholic drink, malt liquors, wines, and the stronger spirits should not be allowed. An intestinal irritation, with palling of the appetite is the objectionable feature of fruit eating; a gastritis or hyperemia of the stomach the reason for not allowing strong drink.

With these restrictions the patient is encouraged to enjoy the pleasures of the table, and he should be impressed with the maxim that poor man's gout can be cured only with the rich man's board.

Concerning the beneficial effects of nutritious and varied food in arthritis deformans, there is no question in the minds of those who have of recent time engaged themselves in the treatment of the disease, and it is a remarkable fact when one recalls that so able an observer as Jonathan Hutchinson has considered its etiology as hereditary gout in the female sex.

Local applications are of temporary value and purely anodyne. The oil of wintergreen or salicylic acid thus used may receive a moment's praise from the patient.

A much better application than either, and probably the best of its class, is the emplastrum hydrargyri United States Pharmacopœia, whose action on both local pain and stiffness is marked. In the disease of the vertebral column and sacroiliac and sacrococcygeal articulations its benefit is decided. It may be freely used, as toxic symptoms of mercurialism do not occur.

Of other treatments than that here described the writer has seen no good results and sometimes evil ones. The hot-air treatment, general and local, electricity, galvanic, faradic and static, electric light bath, poultices, hot-sand bath, mud bath, hot bath, cold bath; ice frictions, Roentgen rays, massage, all of these do not cure arthritis deformans, and entail expense, inconvenience and loss of time without compensatory benefit. Ocean voyages, various health resorts and mineral springs—arsenical; iron, sulphur, saline and alkaline—are so restricted in their usefulness, when we consider the immense number of the victims of this disease in the world, that to hold such resorts a means of cure looks pitiful.

Our remedies for the treatment of articular rheumatism, and gout, do harm when given in arthritis deformans. They do not mitigate the pain; they do so diminish the patient's digestion, weight, and strength so speedily that he grows more helpless. This applies to the salicylate salts and the oil of wintergreen, to lithium, the iodides, colchicum and various coal-tar products.

The syrup of ferrous iodide, recommended by A. E. Garrod, may possess some virtue, but cannot be compared to arsenic when used as here given. Good authorities praise elementary iodine, and also sulphur, but both are feeble props in aiding those who have this disease.

With the means here described arthritis deformans can often be cured; and at times the results are rapid and brilliant. The gloomy prognosis which overhangs the staid and erudite descriptions in our medical literature is founded only on the natural termination of a disease process which has run its course, unopposed by appropriate treatment.

PARATYPHOID; A CASE OF THE HEMORRHAGIC VARIETY.*

BY T. H. EVANS, M.D.,
OF PHILADELPHIA.

In Philadelphia we have typhoid, like the poor, always with us. By the same token this wealth of clinical material ought to be the means of enlarging our understanding of the disease. Its manifestations are not always sure to follow the typical course, and here, as elsewhere, instances of what might be termed paratyphoid, occur.

The hemorraghic form of typhoid fever is the result of Eberthian infection. The disease will follow a fairly ordinary clinical course, with the exception that the fever, while undergoing the diurnal elevation and morning fall, may show less temperature, or a more variable range of it, somewhat of the appearance of what is noted in the general reaction accompanying slight local suppurative processes.

It is known, indeed, that the specific microorganism is recoverable[1] from the rose spots and from most of the viscera, as well as from the functional secretions and excretions of the body, in the usual form of typhoid.

In the hemorrhagic variety, however, during the late second or early third week, sudden and severe, at times, perhaps, insignificant hemorrhages occur from one or many of the special mucous membranes, *e.g.*, the nasal, conjunctival, tympanic, oral, pharyngeal, urethral, vaginal or rectal. The skin may offer a sort of hemic leakage, as noted by Samohrd in three cases.

A particular, local Eberthian infection is the cause of this; for in the hemic discharges, as well as in the tissues firstly concerned, the *Bacillus of Eberth* is freely found, and no evidences of secondary septicemia have been reported.

In the five cases of this hemorrhagic variety of the disease, reported by Samohrd,[2] it was a case of the lightest sort which alone proved fatal. There had been a certain tendency to cutaneous hemorrhage and slight urethral leakage, but the general effects were pronouncedly sthenic.

April 15, 1904, I was called in to the following:

Case.—Miss Emma B. aged twenty-four years. Had been suffering from headache, gastric irritability, constipation, cough, and malaise for two weeks. This day was third of menstruation at proper time, though as usual scanty and painful. History of menstruation begun at fifteen; had had usual diseases of childhood, but no previous attack of typhoid. On examination the viscera appeared in normal relations, except the spleen, which was enlarged from 1.0 cm. to 2.5 cm. in each direction; palpable and tender. Tenderness in right iliac fossa. The spleen continued to be a decided source of annoyance for the next four weeks. At the first, there appeared some bronchial irritation, which did not continue into the next week. Temperature first noted at noon was 38.6° C.

Typical typhoid facies; the patient put to bed at once on suspicion, and cold sponging resorted to, with the administration of dil. hydrochloric acid and salol. For two weeks the fever continued, with a daily range of 37.9° C. to 38.8° C., and higher; at the beginning of the attack 39.6° C. being reached. May 4, the Widal still negative. May 1, there occurred a profuse vaginal discharge of blood, which was not mentioned to me until it had continued, with intermissions, for three days. The girl's mother had thought it possibly a return of the menstrual flow.

The discharge, however, was brighter in color and of a rather different nature. Menstruation had occurred at the proper time two weeks previously. This extraordinary hemic leakage returned off and on during five days. May 3, the temperature in the morning was normal; at 7 P.M. 37.5° C., May 5, the usual subnormal morning record appeared. The typhoid facies no longer was noted, and the Eberthian infection apparently had been subdued. Treatment continued with cold sponging, and dil. hydrochloric acid. But the salol was exchanged for protonuclein. Splenic enlargement and tenderness remained a prominent feature. The patient seemed much exhausted by the disease, more so than in

* Received for publication May 25, 1904.

proportion to the amount of fever, which latterly had been moderate, I think, due to the cold water treatment. The appearance of the patient was asthenic rather than sthenic, after the second week. Light diet was ordered on May 13. A recurrence of slight temperature the next day, and a hint of duskiness in the face, warned us that it was too soon. Milk diet was again ordered. The bowels required daily enemas, from the first week. Finally, on May 18, an increase of diet was accomplished, and from then on the return of health has been assured. The Widal was positive when applied May 16. No further vaginal hemic leakage has since been noted.

This is one of a great number of cases of enteric fever I have seen showing very moderate temperature range. In regions where typhoid infection is prevalent it may be possible that many cases of Eberthian infection are so atypical as to escape diagnosis. The clinical progress of the case, however, ought to cause its proper recognition.

One fever case, which I had in March, gave a negative Widal, but showed unmistakable typhoid symptoms, notwithstanding a temperature range that never passed above 38.0° C. It was impossible in this case to resume solid diet until five weeks following the initial febrile stage, although the attempt was twice made and given up on account of immediate return of temperature, which had been subnormal.

As to the pathology of the hemorrhagic form of Eberthian disease there is obscurity of opinion. Clinical study will be in advance of an exact determination of the facts. Some reaction probably does occur in the parenchyma of the mucous structures of the body other than the mucosa intestinalis.

Samohrd suggests the possibility of a "more than commonly virulent species of the specific micro-organism." This, attacking the walls of the smaller blood vessels, would predispose to hemorrhage through the degenerated areas in their continuity. Very few comments on the etiology can be found in the literature of this subject. I have thought it possible that in the cycle of development of the bacillus the elimination of toxins could be different in degree or kind. The individual's reaction may be modified according to idiosyncrasy.

2 Sbornik Klinicky, Tomo V, fasc. 1, 1903, and abstracted in Il Policlinico, Rome, No. 21, 1904.

Diphtheritic Paralysis and Antitoxin.—The cases reported by other observers and those that were under his own care, led J. Comby (*Arch. de Méd. des Enfants*, July, 1904) to advocate the use of diphtheritic antitoxin in the case of all children affected with diphtheritic paralysis, whether or not they have been treated with this for the original disease. In the first place, there is no risk. In the second place, one is not certain that the original infection has entirely exhausted its virulence. The beneficial and quiet results obtained in arresting the progress of cases of diphtheritic paralysis and effecting a cure in three to ten days form ample justification for the above treatment.

INTESTINAL OBSTRUCTION FOLLOWING APPENDICITIS OPERATIONS. REPORT OF EIGHTY-SIX CASES.

BY CLARENCE A. McWILLIAMS, M.D.,
OF NEW YORK;
INSTRUCTOR IN SURGERY, COLUMBIA UNIVERSITY; SURGEON TO TRINITY HOSPITAL; ASSISTANT SURGEON TO PRESBYTERIAN HOSPITAL.

(Continued from Page 406.)

THE LITERATURE AND UNPUBLISHED CASES.

In a paper published by Dr. Lucius W. Hotchkiss (*Annals of Surgery*, November, 1901), there are reported all the cases appearing in the records of the Transactions of the New York Surgical Society since 1893. In this series there were fifteen recoveries and six deaths. Dr. Ellsworth Eliot, Jr., in the Medical News of September 26, 1903, reports three cases, two recoveries and one death. At a meeting of the New York Surgical Society held December 9, 1903, three cases were reported. One by Dr. Hotchkiss followed several weeks after the appendicectomy, in which there was also a small abscess. In the successful operation for obstruction, an abscess was opened in the pelvis. This abscess had caused adhesions, which themselves had produced an angulation in the gut. Dr. Brewer reported a second successful case following a year after the original operation, the obstruction having lasted one week, where seven inches above the cecum a band had caused a kinking of the intestines. The third successful case was operated upon by Dr. Willy Meyer, eleven days after the original operation. In the second operation nothing was done but the opening of a secondary abscess. The adhesions about this abscess or possibly the pressure of the abscess had caused a kinking of the intestines.

Dr. R. H. Follis, Jr. (*Johns Hopkins Hospital Bulletin*, 1903, XIV, 86-88), reports operating for appendicitis abscess. After three days obstruction developed, for which he performed an intestinal fistula. Patient did well for eighteen days, when a second obstruction developed, due to occlusion of another loop proximal to the site of the loop first opened. For this likewise a second fecal fistula was made. Normal bowel-movements were soon established and the two artificial ani eventually closed of themselves.

L. Bérard (*Bull. Méd.*, Paris, 1902, XVI., 286-288) successfully operated on a case of obstruction seven years after an undoubted case of appendicitis, where he found many adhesions and a complex volvulus.

Otto Meyer, of Hamburg, reports in the *Deutsche Praxis* (München, 1901, X., 412-414) operating upon an appendix abscess. A more or less general peritonitis ensued, resulting in what were thought to be a number of localized abscesses. Intestinal obstruction set in two weeks after the first operation, and on account of the patient's serious condition, operation was not performed. In its place a needle was inserted into the dilated intestines six times in thirty-six hours, each time with relief of the obstruction. No operation was done and the patient made a perfect recovery.

A. M. Cartledge (Louisville monthly *Journal of Medicine and Surgery*, 1900, VII, pp. 1-4) publishes a case illustrative of a different type than the preceding. Two days following the opening of an appendix abscess, he had to make an artificial anus for intestinal obstruction. Three months later he operated to relieve this obstruction, and found the difficulty to be due to contracted adhesions which had narrowed the lumen to the size of a lead pencil. In the discussion which followed the reading of this paper, Dr. W. C. Duncan said that he had had six cases of obstruction following within a few days after appendicitis operations. In all these he had made fecal fistulæ. Four out of the six died.

Broca writes a very interesting article, reporting six cases, in the *Gaz. hebd. de Med. et Chir.*, 1901, XLVIII., 445-450. He divides the cases into two classes: First, those cases of appendicitis which develop obstruction before the original wound has healed—"early" obstruction; second, "tardy" obstruction; this suddenly appears after a period of perfect health of varying duration, in a person who has already had an appendicitis, either suppurative or non-suppurative, previously operated upon or not. He cites three cases in each class, and comes to the conclusion that different operative measures are necessary in each class.

First class cases: Appendix abscess opened July 4, 1896, appendix not removed. Six weeks later obstruction preceded by progressive constipation lasting four days; operated upon by median incision. Adherent band divided. No relief. Death followed. Autopsy revealed mass of adherent intestines, matted together, in the pelvis. Second case almost a counterpart of the preceding. Localized abscess opened December 9, 1899; appendix not removed. Fifteen days later gradually increasing obstruction. Operation by median laparotomy showed multiple kinkings in an adherent mass of intestines. Death. Autopsy in addition showed a small secondary abscess. In the third case a different method of procedure was employed. On February 6, 1900, an appendix abscess was opened, appendix not removed. Six weeks later obstruction developed. Median wound not made, but the original wound was enlarged. Two openings were made in two adherent coils of intestines, but nothing but gas came out. Adhesions internally carefully separated and a band of omentum found to constrict intestines. Feces then came through the fistulæ. Recovery. Two months later an attempt to close the fistulæ resulted fatally.

Second class of cases represents "tardy" obstruction, which comes on after a longer or shorter period of perfect health, following complete recovery from an appendicitis. The first case was operated upon in December, 1897, and a chronically inflamed appendix removed. Fecal fistula resulted, but closed spontaneously later. On July 1, 1898, operation for obstruction of three days' duration. Wound was reopened, but nothing was found there. He then made median opening. A loop of small intestine was encountered, twisted into a U-shape by a double band in the mesenteric edge. This latter divided. Obstruction not relieved. Death. Autopsy showed an additional obstruction caused by a twisted loop of small intestine, adherent behind the ascending colon.

The second case was operated on July 25, 1898, for a non-suppurative appendicitis. Quick convalescence. Well until February 19, 1899, when obstruction set in. Operation four days later. Median laparotomy. Band found compressing the ileum at its junction with cecum. Obstruction seemed relieved, but patient died a few hours later of shock. The third patient had had seven years previously a severe attack of appendicitis, which was treated medically and from which he recovered perfectly. July 7, 1900, he was seized very suddenly with all the symptoms of obstruction, for which he was operated on in twenty-four hours. Median laparotomy. Band found attached by one end to the intestine, and by the other to the pelvic wall, causing bending and compression of the loop, the two extremities of which were adherent. Division of the band and separation of the adhesions. A second compressing band was found in the right iliac fossa. Recovery. Broca comes to the conclusion from these cases, that cases belonging to the first category had better not be operated upon by a new median incision, but a distended loop of intestine searched for in the old wound, which, when found, should be opened, thus forming an artificial anus without opening the general peritoneal cavity. Later on, after many of the adhesions had become absorbed, the fistula could be closed, if it had not done so of itself. He thinks that the mortality would be much less by using this plan of procedure. In the "tardy" cases he unreservedly recommends a median incision below the navel.

J. B. Murphy (*Chicago Clinical Review*, 1895, V, 645) reports three cases all recovering after operation: (1) In August, 1895, he opened an appendix abscess, not removing the appendix. Subsequently the patient had several severe attacks of almost complete obstruction, for which he operated in April, 1896. He found the cecum adherent to the abdominal wall. A loop of ileum had become wedged in between the cecum and the abdominal wall, and was consequently much compressed. Recovery. (2) In December, 1894, he drained an appendix abscess. In February, 1895, he removed the appendix, following which the patient had four or five attacks each month of abdominal distention, vomiting, severe constipation, the attacks becoming gradually more severe. In June, 1896, operation disclosed a loop of ileum bound down between the cecum and small intestine, the part of the intestine proximal to the constriction being distended, the distal portion contracted. Recovery. (3) In June, 1895, a patient had a severe attack of appendicitis from which he was in bed four days. Following this he had several other attacks of the same difficulty. In January, 1896, after an attack of complete obstruction, he was operated upon. On separating

a mass of adherent intestines, there was found an almost completely flexed loop. Recovery.

Brunton ("Transaction of the Clinical Society," London, 1893, XXVII, 196) reports a case of obstruction due to narrowing of the lumen, the result of recurring appendicitis. The patient had the first attack in May, 1892, followed by five attacks. The last one was in May, 1893. On September 1, 1893, appendicectomy. Twenty-four days thereafter the patient was operated upon for an obstruction of two days' duration, in which there was fecal vomiting. He found a mass of adhesions producing kinking of a loop. Recovery.

G. Marion (*Gazette des Hôpital*, Paris, 1900, p. 1439) has published an exhaustive article on the subject, reporting five cases with one recovery: *Case I.*—Operation, June, 1900, for an acute appendicitis. In September following, operation for obstruction, preceded for twelve days by obstinate constipation, for four days by total obstruction, and for twenty-four hours by fecal vomiting. Median laparotomy. Small intestine some distance from cecum found much distended. Beyond this point, near cecum, intestine was collapsed. Between these two portions in the right iliac fossa was a mass of adherent small intestine, folded and twisted on each other tightly. Recovery. *Case II.*—Operation, May 1, 1900. Gangrenous appendix with general peritonitis. Thirteen days later symptoms of obstruction. Operation, May 17, 1900.—Original wound opened. All the bowel found adherent, twisted, and compressed with no possibility of their being liberated. Cecum incised. This simply produced emptying of the cecum itself. Incision in a coil of small intestine likewise produced only a limited evacuation of the contents of the immediate neighborhood. Autopsy showed practically the whole extent of the intestines agglutinated. *Case III.*—Operation, March 30, 1900, for appendicitis of two days' duration. April 11. Vaginal puncture for abscess in the cul-de-sac. April 21. Operation for obstruction of three days' standing. Findings—great mass of generally agglutinated intestines. Artificial anus made. Death. Autopsy showed the same unrelievable condition present as on operation. Marion here remarks that in many of these cases with a great mass of adherent bowel involving almost its whole extent, it is most difficult to decipher the exact cause as well as the exact site of the obstruction—it may be produced by tension, by bending, by strangulation, by volvulus, etc. These cases result from a general septic peritonitis, and an artificial anus seems the only resource. Another class of cases shows obstruction to be due to localized adhesions, in illustration of which he cites two operations. *Case IV.*—This patient had had a number of years before an appendicitis, for which there had been no operation. In July, 1900, operation for obstruction of several days' duration. The small intestines were found plastered to the cecum in an almost inextricable mass. Death. *Case V.*—This patient had had three antecedent attacks of appendicitis, the last one a month previously. Obstruction existed for four days. Operation.—In cecal region many dense adhesions. Artificial anus. Death. Autopsy showed in the mass of adherent intestines about the cecum a volvulus absolutely constricting the bowel.

Dr. Samuel Lloyd has had four cases of obstruction occurring at varying intervals after a primary appendicitis operation, none within two weeks thereafter. All recovered after operation. *Case I.*—An intestinal coil was adherent to and wound about another loop so as to produce a constriction and total obstruction. *Case II.*—In this case the omentum, forming part of the abscess-wall, was so tightly wound about a coil as to shut off the fecal circulation. *Case III.*—Gangrenous appendix removed. Three weeks after the primary operation, complete obstruction. Operation disclosed the fact that the adhesions in the wall of the old abscess had loosened up, and through the opening thus caused a loop of intestine had slipped, producing a strangulated hernia. *Case IV.*—Abscess alone opened at the primary operation. At a subsequent operation for obstruction, the appendix was found tightly wound about a coil and very adherent, producing obstruction at this point.

Dr. F. H. Markoe has had the three following unpublished cases: *Case I.*—Male, aged forty years. Operation in 1886 for perityphlitic abscess without removal of the appendix. In September, 1894, operation for obstruction, due to adhesions binding the ileum to the old appendix site. Recovery. *Case II.*—Boy, aged eleven years. Operation for acute suppurative appendicitis, September 14, 1889. One month later operation for obstruction due to adhesions resulted fatally. *Case III.*—Girl, aged thirteen years. Operation for suppurative appendicitis, November 29, 1895. Four days later an operation for obstruction resulted fatally.

Dr. Arthur L. Fisk operated upon a case of gangrenous appendicitis with a general peritonitis. Six days later a secondary abscess was opened. Twenty days after the first operation, acute obstruction. Operation disclosed complete kinks in two different places buried in a mass of adhesions. Recovery.

Dr. J. B. Lee gives me the following case: Interval appendix operation June, 1903. No pus, but a few adhesions found. No drainage. Well until November 14, 1903, when he was seized with abdominal pains and vomiting. Large result from high enema. Obstructive symptoms then gradually developed. November 17, he had had no passage of feces or gas for two days. Fecal vomiting set in and distention. Patient having previously refused operation, consented on November 17. Median incision. A band was found stretching from the mesentery, passing over the ileo-cecal junction which it compressed, attaching itself to the abdominal wall. Behind this band a loop of ileum had wedged itself in. The large intestine was collapsed and the small was much distended. After division of the band, gas passed

onward into the collapsed intestine. Death in two days was apparently due to peritonitis, although the bowels had not acted after the operation.

Dr. L. W. Hotchkiss has operated upon these two unpublished cases: *Case I.*—Male, aged 2½ years. Operation, July 21, 1903, on the fifth day of the attack. Appendix found with gangrenous tip surrounded by a small abscess. A secondary abscess opened behind and above cecum. Operation for obstruction, August 7, 1903. Median incision. Angulation found at the cecum due to adhesions. Recovery. *Case II.*—This is a very interesting case of immediate obstruction. Male, aged twenty years. Operation, November 14, 1903, acute gangrenous appendicitis with abscess and progressive peritonitis. On account of intractable vomiting, advancing sepsis, and no bowel-movement, operation two days after the first operation. Median laparotomy. Some free, dark, foul fluid in peritoneal cavity. A mechanical obstruction was found due to adherent band on right side producing a kink. Recovery from this procedure. Ten days later a second obstruction developed suddenly and was rapidly fatal without operation. In addition both wounds were infected and patient was septic.

Dr. Robert Abbe has had five cases of obstruction following appendix operations. All recovered after operations for the obstructions.

Dr. Joseph A. Blake has kindly given me the following three interesting cases: *Case I.*—M. A., female, aged thirty-one years. Operation for chronic appendicitis five weeks previously (operator unknown); no drainage. Obstruction had lasted five days. Operation disclosed the intestines obstructed in three places by fairly strong bands. Adhesive and purulent peritonitis in lower half of abdomen. Leakage of appendical stump. Death in forty-eight hours from sepsis. *Case II.*—J. T., male, aged thirty-two years. First operation January 8, 1901, for appendical abscess. Appendectomy and drainage (tube). Second operation February 21, 1901. Celiotomy for a secondary abscess, situated just below the liver, imbedded in a mass of adhesions. Drainage. The third operation was on March 26, 1901. Intestinal obstruction found, due to adhesion of loop of small intestine to abdominal wall, and a resulting volvulus. Resection of three inches of bowel and end-to-end union with Murphy button. Death on third day from peritonitis. *Case III.*—This case is one of acute intestinal obstruction due to bands, resulting from attacks of recurrent appendicitis without operation. At the time of operation patient was also suffering from appendicitis in the third day of the attack. C. A., female, aged eighteen years. Operation revealed the appendix acutely inflamed, strictured, and distended, fresh adhesions. A loop of ileum, twelve inches long, found strangulated under a band (adhesion), and gangrenous. Appendectomy; resection of gut; end-to-end union Murphy button. Recovery.

Dr. C. L. Gibson has reported to me this unpublished case: J. H., aged eleven years; operation August 13, 1902, for a first attack of appendicitis of three days' duration. There was a gangrenous appendix and free pus in all parts of the abdomen. Drainage was accomplished by an incision along the outer border of each rectus and a third in the epigastrium. Continuous irrigation was maintained for twenty-four hours. Marked improvement followed the operation, and patient was getting progressively better when on the ninth day vomiting and failure of bowel-movement set in. Operation next day. Cecum was found distended with fluid feces. Source of the obstruction not sought for, an artificial anus being made in the cecum. Temporary improvement, but death next day.

Kocher, in an article on ileus in general (*Mitteil. aus den Grenzgeb. der Med. und Chir.*, 1898, p. 227, Vol. 4), reports two cases of obstruction in patients who had had previously attacks of appendicitis unoperated upon, both due to bands from old adhesions. One patient had symptoms of obstruction for ten days, and gangrenous gut was found. This patient finally recovered, although convalescence was complicated with an abscess. The second case had a firm band binding the intestine so firmly as to completely obstruct its lumen. Recovery.

Dr. George E. Brewer has kindly furnished me with the following two unpublished cases: *Case I.*—L. R., aged thirteen years. Acute appendicitis with abscess fourteen months ago; convalescence delayed by prolonged suppuration. Admitted to Roosevelt Hospital, November 3, 1903. Sickness began five days ago with umbilical pain, vomiting and general weakness. Bowels moved once following enema. No flatus nor movement since. On admission, moderate distention, generalized tenderness; temperature 101° F., pulse 120 and weak. Median incision six inches. Transverse colon collapsed and traced downward to right inguinal region, where a dense band was found passing from appendix stump to pelvic basin, beneath which was found about three inches of ileum. Constricted loop, dark chocolate color. Bowel above this loop distended. Loop freed by division of band, stitched near surface wound, injured intestine guarded by omental reinforcement. Wound closed with drainage. Recovery. *Case II.*—A. B., aged twenty-seven years. Has had six previous laparotomies. One for Cæsarean section, one for acute appendicitis, one for ventral hernia, one for "abscess," and two for intestinal obstruction. Admitted November, 1903. Complained for one month of abdominal pain and slight distention with occasional vomiting. Bowels moved with difficulty. For past six days no movement or flatus. Very tender point to left of umbilicus; continuous vomiting. Temperature, subnormal; pulse, 130 and weak. Ten-inch incision to left of median line. Everything densely adherent. Three points of acute angulation found, one almost completely occluding lumen. Intestine distended above this point, collapse below. Adhesions separated and gut freed. A

long rusty needle found penetrating omentum and transverse colon beneath point of greatest tenderness. Recovery uninterrupted.

Lapeyre, in the French Congress of Surgeons (*Revue de Chir.*, November, 1903, p. 628), reports three patients who had had a number of attacks of appendicitis previously, unoperated upon. All were subsequently operated upon for obstruction, from which one recovered.

Sonnenburg (*Centralblatt für Chir.*, No. 50, 1903, p. 1378) in the proceedings of the Berlin Surgical Society reports ten cases of obstruction. In four cases it followed operations for appendicitis where pus was found, while in six cases obstruction followed operations done in the interval. In none at the time of the second operation for obstruction was there peritonitis present. The mortality is not reported.

Dr. Andrew J. McCosh reports in the "Presbyterian Hospital Reports" three cases of postoperative obstruction. All recovered from the operations for obstruction at his hands, one patient dying six months later, after an operation for obstruction, in a western city.

Dr. John Rogers, Jr., kindly furnishes me with following complicated case: Male, aged nineteen years; operation for appendix abscess September, 1902. After a hearty meal, September 29, 1903, sudden attack of "cramps." The next day he began to vomit, passed some gas, but no feces. The next three days he continued to vomit bilious matter and passed no gas nor feces. Seen by Dr. Rogers on October 3, 1903, for first time, when the only complaint was the vomiting of yellowish-green material. Enemata previously given had resulted in the passing of some foul, fecal-smelling, watery movements. Belly found soft and concave, with no tenderness anywhere. Temperature, 101° F.; pulse, 125. Expectant treatment for two days, in which constipation and vomiting persisted. Operation, October 5, 1903. Median opening. Little or no intestinal distention. Exploration of the appendical region showed a dense fibrous band under which the intestine was tightly constricted. This band started from the ascending colon between it and the ileum, and passed up and back toward the spine, and was about two or three inches long. As it was divided, the upper and inner attachment was found to be the free border of the great omentum. The liberated gut when drawn out showed a transverse line of gangrene about one-quarter of an inch wide. The constricting band was so narrow that it had simply divided the gut transversely like a cord, so that very little trimming of the ends was necessary in order to make an end-to-end union with a Murphy button. The constriction was approximately eighteen inches down from the beginning of the jejunum. Recovery uneventful. Button passed on twenty-fifth day.

The total number of cases reported in this article is eighty-six. Of these fifty-seven recovered after operations for the obstruction, and twenty-nine died, giving 66.3 per cent. of recoveries, and 33.7 per cent. of deaths.

Five cases had more than one attack of postoperative obstruction, viz., Johnson's case (reported New York Surgical Society, April 11, 1900) had three attacks, two operations for obstruction had been required within the year following the original operation for appendicitis, death resulting from a third attempt to relieve an obstruction which had developed in the course of the third year; McWilliams's first case in this article had two attacks with recovery after operations.

Hotchkiss's case had two attacks, the patient dying in the second attack without operation; Brewer's patient had three attacks, with recovery after three operations; McCosh's patient had two attacks, with death after the second operation for obstruction.

From this it is seen that .8 per cent. of those who had survived one attack of obstruction suffered others.

The location of the obstruction was given in fifty of the cases. In every one it was situated in the small intestine. The cause of the obstruction was given in fifty-three cases, and they are as follows: Constrictions by bands in twenty-eight patients, volvuli in ten; kinkings, or angulations, in eleven; and internal hernias in four cases. Gangrenous gut was encountered in five cases, necessitating resection, resulting in three recoveries and two deaths.

A fact to be noted is that obstruction occurred after the interval operation in eight cases. While no attempt was made to tabulate all the cases in the literature occurring in patients who had had no operation for attacks of appendicitis, it may be remarked that in this series there were nine such cases.

The time of the occurrence of the obstruction after the appendicitis, or after the operation for it, is given in fifty-four cases. It may be summarized as follows:

In first week, six cases; in second week, eight cases; in third week, eight cases; in fourth week, three cases; in fifth week, three cases; in sixth week, two cases; in seventh week, one case. From the third month to the twelfth, seven cases; between the first and second years, ten cases; between the second and third years, three cases; between the third and fourth year, one case. One case occurred in the seventh year and one in the eighth year.

In concluding this report of cases, I wish to acknowledge my appreciation of the courtesy and generosity of the various surgeons who have so kindly furnished me with their cases, and to record my thanks to them all, collectively and individually.

It is noteworthy that in the innumerable operations for appendicitis, obstruction occurs so infrequently, and in the future we may expect a still smaller mortality from this complication, due to the earlier recognition of the original disease as well as the early operation for this complication at its inception, before the development of gangrenous bowel or peritonitis.

CONCLUSIONS.

1. The rarity of intestinal obstruction in comparison with the innumerable operations for appendicitis is noteworthy.

2. Obstruction may follow an attack of appendicitis which has not undergone operation. Nine such cases occurred in this series of eighty-six cases, or ten per cent.

3. Obstruction may follow the "interval" operation. Eight cases, or nine per cent., belong to this category.

4. Obstruction is most apt to follow appendicitis with abscess formation. Sixty-nine, or eighty-one per cent., were of this class. Hence the necessity for early operation.

5. Mechanical obstruction may come on within a short time after the appendicitis operation, when the differential diagnosis from that due to peritonitis may present great difficulties. When in doubt, operate, for many patients have undoubtedly died, unoperated upon, with an unrecognized mechanical obstruction (with or without peritonitis) where the erroneous diagnosis was made of simple, uncomplicated peritonitis.

6. Obstruction may occur years after the original attack, or operation (*e.g.*, ten cases occurred in the second year), when it may come on suddenly in perfect health, or preceded by a period with symptoms denoting "partial" (chronic) occlusion, the right interpretation of which symptoms, from a prophylactic standpoint, is of the greatest importance.

7. There may be several attacks of true, mechanical obstruction. In the above series of eighty-six cases, several attacks occurred in five, or .8 per cent., of the fifty-seven patients who survived the first operation for obstruction.

8. Of the eighty-six patients, fifty-seven, or 66.3 per cent., recovered after operations for obstructions. Twenty-nine patients, or 33.7 per cent., died.

9. The small intestine was occluded in all of the fifty cases where it was noted.

10. The cause of the obstruction was given in fifty-three cases as follows: Constrictions by bands in twenty-eight patients; volvuli in ten; kinkings, or angulations, in eleven; and internal hernias in four cases.

11. Gangrenous bowel was encountered in five cases, necessitating resection, resulting in three recoveries and two deaths.

12. We may expect a much smaller death-rate in the future, due to the earlier recognition of the symptoms and their more prompt relief by operation. Fecal vomiting should not be waited for.

13. Prophylaxis consists in operating upon appendicitis before the formation of pus, the use of as little drainage as possible, and the least possible amount of handling of the intestines, at the time of operation.

14. Vigorous abdominal massage with elevation of the hips may avert an impending obstruction. Frequent change in patient's position is likewise recommended.

15. Since the exciting cause is in many cases an attack of acute indigestion, patients should have their diet carefully regulated for from four to six weeks after an attack of appendicitis or after an operation.

50 East Fifty-third Street.

A CASE OF LUDWIG'S ANGINA.[1]

BY C. M. HARRIS, M.D.,
OF PHILADELPHIA.

OUR committee has asked me to report to you some facts relating to a case of Ludwig's angina, which was recently under my care. As the disorder is not common, I have thought best to give you a brief description of it, which I have extracted from standard works on surgery, which, however, devote very little space to the subject.

It is generally defined as a streptococcus infection about the submaxillary gland, and alveolar tissue beneath the mucous membrane of the floor of the mouth and upper portion of the neck. It may arise in a perfectly healthy man after an infectious fever or from trauma. As a result of the infection there is a cellulitis about the submaxillary gland which tends to the formation of a slough rather than pus. This cellulitis is said by one authority to follow the infection of a lymph node over the gland, but as to how this lymph node became infected no explanation is given.

The symptoms are some local discomfort followed in two or four days by swelling and pain. The tongue becomes swollen and painful, opening of the mouth is attended with difficulty. The tissues about the frenum are distended. Pressure causes considerable dysphagia, and there is sometimes great salivation and dyspepsia. Edema of the glottis has occurred with fatal result. In some instances high temperature and symptoms of septicemia or pyemia are present; gangrene is sometimes an accompanying factor.

As to treatment, all authorities recommend early incision, with removal of any gangrenous tissue. This may be followed by applications of carbolic acid. The constitutional treatment is that of septicemia.

As to the case mentioned, it was that of a young man, twenty-two years of age; family history was negative and he had always been generally healthy. On August 25 he went to a public bath and remained in the water for two or three hours. The following day he complained of some pain in the right ear and some swelling in the right submaxillary region. On the second day these symptoms were more pronounced. On the third day I made my first visit and found the patient sitting up, with head inclined backward, face flushed, and with a hard tense swelling in the submaxillary region on the right side and about the base of the tongue. This swelling was unattended by external redness or any apparent heat. The mouth could be partly opened with great difficulty. This revealed a thick coating on the dorsal surface of the tongue and some of the buccal mucous membrane. The anterior portion of the tongue was forced

[1] Read before the Northwest Medical Society, of Philadelphia.

upward, showing edematous swelling about the frenum and floor of the mouth. The orifices of the submaxillary and sublingual glands were quite prominent. The patient stated that the pain was worse than on the preceding two days. The temperature was taken and found to be 100° F. and was not higher at any time during the illness.

On the morning of the fourth day the condition seemed stationary. Twelve hours later the swelling had extended posteriorly beyond the angle of the jaw, and the pain in the ear was almost intolerable. Attempts at aural examination revealed nothing except much swelling of the tissues about the external auditory canal. An opiate was given and the patient passed a comfortable night. The fifth day showed some diminuation of the swelling generally and the tongue began to clear. The ear gave very little pain. By the seventh day the swelling was practically gone, the tongue cleared, and the mouth now capable of being fully opened, presented a nearly normal appearance.

On the ninth day some pus was discharged from the affected ear; the external auditory canal showed considerable swelling and redness, but as my skill as an otologist was quite limited, I have never determined whether the pus was formed in the middle or external ear. After a week the discharge ceased and has not reappeared. Patient has since been in perfect health.

Not being convinced of the necessity of immediate incision in this case, the plan of treatment followed was an expectant one. During the first four days of my attendance one-quarter grain doses of calomel were given hourly for eight to ten hours a day and followed by salines. Desiring to demonstrate the value of a sample package of a quite popular preparation of glycerinated clay, a fresh application of this was made every twelve hours until recovery took place. As previously mentioned, an opiate was given on one occasion to relieve pain in the ear. Subsequent treatment of the aural discharge consisted of syringing with peroxide of hydrogen and an alkaline antiseptic solution.

If we are to give drugs the credit for a cure in this case, I must say I am prejudiced in favor of the calomel, and am inclined to think that lead water and laudanum and ice would have acted quite as well as the glycerinated clay.

I consider the prominent factors in this case to be the obscurity of the cause, and the involvement of the ear and the gratifying result of the conservative treatment. However, owing to certain anatomical and physiological reasons, I have not a doubt that prompt incision would be the safer course in a majority of such cases.

Eye-Strain and Inebriety.—Drunkenness has been added to the already imposing list of maladies which oculists pretend to cure by the relief of eye-strain. The craving for alcohol may be, and often is, a nervous affection, and if the source of the affection is in the eyes, according to the argument of a Chicago oculist at a recent conference in Milwaukee, resort must be had to glasses that cheer and not inebriate.

ENDERMOL, A NEW VEHICLE FOR OINTMENTS.

BY PROF. VIRGIL COBLENTZ, PH.D., PHAR.M., F.C.S., OF NEW YORK.

Endermol, a combination of stearic acid amide and paraffin hydrocarbons, forms an almost white mass of about the consistency of lard, inodorous, of neutral reaction and fusing at 78° to 80° C. The iodine absorption number is 16.98, while that of lard averages about 62, a point in favor of the former as a vehicle for iodine.

When exposed to the air and sunlight under adverse conditions, samples of endermol retained their color, consistency and blandness. When applied to the skin by inunction, endermol forms a smooth, soft, unctuous mass which is readily absorbed. This may be demonstrated comparatively, by applying a little of petrolatum, lanolin and endermol in separate portions, by inunction to the skin and noting the time required for absorption. Furthermore, applications of endermol ointments of iodine (without potassium iodide) and also aconite, were followed by the excretion of iodine in the urine after about five hours in the former, and the characteristic dryness of the throat in the latter.

Rancidity in fats is due to hydrolysis or splitting up of the esters of the fatty acids, with liberation of the free acids. To the presence of these the irritating properties of rancid fats are due. In endermol, consisting chiefly of stearic amide, we have a stable fatty acid derivative which is not decomposed under any conditions through the action of light, air, moisture or such chemicals as are usually employed in ointments.

To demonstrate the adaptability of endermol as a vehicle for ointments, mechanically as well as chemically, such substances as the yellow and red mercuric oxide, yellow and red iodide of mercury, zinc oxide, lead subacetate and carbonete, ichthyol, tar, vegetable extracts and mercury were prepared. All of these yielded smooth, uniform ointments which showed no change whatever upon exposure.

The use of petrolatum, as is well known, is restricted to that of a dressing and this to a limited extent owing to its immiscibility with water, certain chemicals and galenicals.

Lanolin, an excellent vehicle, is objectionable because of its stickiness and toughness and when combined with animal fats (as in lanolin crême), such ointments become rancid and offensive.

There is nothing so objectionable to either the physician or pharmacist as a rancid ointment. While lard or other animal fats may originally have been anhydrous and benzoinated, yet rancidity ensues sooner or later, particularly so when aqueous fluids have been incorporated, as frequently is the case in ointments. Aside from the irritant action, chemical reaction of the liberated fatty acids upon the medicinal agent follows.

Again, lard substitutes consisting of mixtures of suet or tallow or cotton-seed oil stearin, with cotton-seed, sesame or cocoanut oils, are not only open to the same objections, but also the possible

presence of alum, alkalies or water, which render them still less desirable.

Because of its blandness, pliability and freedom from stickiness, endermol is especially adapted as a lubricant for massage treatment, always leaving the skin soft and pliable.

To sum up, the advantages of endermol as an ointment vehicle, are: Absolute freedom from any tendency toward rancidity, although as much as 15 per cent. of water may be incorporated. Ready penetrability and absorption. Pliability, smoothness and fredom from stickiness. Freedom from irritating properties.

A SIMPLE AND ACCURATE METHOD FOR ESTIMATION OF SUGAR IN THE URINE.[1]

BY HARVEY G. BECK, M.D.,
OF BALTIMORE, MD.;
ASSOCIATE PROFESSOR OF CLINICAL MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS.

THE usual method employed for the estimation of sugar in the urine by means of Fehling's solution is fraught with considerable difficulty and the results obtained are often far from accurate. The length of time required to make an estimation, the possibility of other substances being present in the urine, besides glucose, which will reduce Fehling's solution at the boiling temperature, the difficulty of definitely determining the end-reaction, and the necessity, in case of error, of repeating the entire process are all factors which tend to make this method inexpedient. It is for this reason that the writer has introduced a more simple and practical method which is scientifically accurate and requires much less time.

The equipment consists of (*a*) a beaker; (*b*) four centrifugal tubes graduated at 2 c.c.; (*c*) a pipette of 2 c.c. capacity, graduated into twentieths c.c.; (*d*) a wire tube-holder to support the tubes when placed in the beaker, and (*e*) a centrifuge (which is not absolutely necessary).[2]

Method of Application.—The beaker one-third filled with water, or enough to cover the graduation mark on the tubes when placed into the beaker, is placed over a Bunsen flame. The centrifugal tubes are filled to the graduation mark (2 c.c.) with standard Fehling's solution, which is made according to the following formula:

1. Copper solution
   - Cupric sulphate..... 34.64 grams.
   - Distilled water..... 500.0 c.c.
2. Alkaline solution
   - Sodium and potas. tartrate... 173.0 grams.
   - Potassium hydrate..... 125.0 grams.
   - Distilled water..... 500.0 c.c.

Mix equal parts of the two solutions.

The tubes are next placed in the tube-holder and transferred into the beaker. They should be numbered 1, 2, 3 and 4 respectively, according to their position in the tube-holder. When the water boils remove the tubes and, by means of the pipette, add the urine in quantities of 1/20 c.c. Begin by adding 4/20 to tube No. 1 and increase the quantity by 1/20 in each successive tube. For example, 4/20 are added to tube No. 1, 5/20 to No. 2, 6/20 to No. 3 and 7/20 to No. 4.

Care must be exercised in adding the urine. In order to measure accurately these small quantities the index finger, which must be dry, is placed over the upper outlet of the pipette to control the discharge of the urine. Before discharging the urine touch the wire of the tube-holder with the tip of the pipette to release the urine which may have collected on the outside of the orifice, then place it in tube No. 1 in such a manner that the tip will touch the side just above the surface of the reagent, and remove by drawing it along the surface of the tube to the top. Proceed in the same manner with the remainder of the tubes. The tubes are next violently shaken in order to thoroughly mix the urine and the reagent, after which they are returned to the beaker and allowed to remain in the boiling water for three minutes. They are then removed and the red cupric oxide is allowed to precipitate by standing, or precipitation is facilitated by centrifugalization. In the latter method due care must be taken that the order of the series of tubes is not disturbed. The color in the tubes is now observed, and if the Fehling's solution in No. 4 is not completely decolorized, 4/20 c.c. of urine is added to each tube, increasing the amounts respectively to 8, 9, 10 and 11-twentieths c.c., again treating them as before. These steps are repeated until complete decolorization is observed. The first tube in the series which is completely decolorized is chosen and 20 divided by the number of twentieths c.c. which have been added to this tube gives the percentage of sugar present.

To illustrate: 2 c.c. Fehling's solution are reduced by .01 grams of sugar; 1 c.c. of urine contains twenty-twentieths (20/20) c.c.

Suppose sixteen-twentieths c.c. of urine reduce 2 c.c. of Fehling's solution, then the number of twentieths c.c. (16) required will have contained .01 grams of sugar.

$$16 : .01 :: 20 : \times$$

$\times = .0125$ (the amount in grams of sugar in 20-twentieths or 1 c.c. of urine.

If 1 c.c. of urine contains .0125 grams of sugar, 100 c.c. contains 1.25 grams or 1.25 per cent.

$$1 : .0125 :: 100 : \times$$

$\times = 1.25$ per cent.

To determine the end-reaction more definitely 1/20 c.c. of urine is added to each tube after sedimentation in such a manner as to form a thin layer on the surface, after which the tubes are returned to the beaker without agitation. A yellow ring of cuprous oxide appears near the surface in those tubes in which reduction is incomplete.

The above method will suffice for all practical purposes. When, however, a scientifically accurate determination is desired the following measures should be added in case less than 10/20 c.c. of urine is used to reduce the Fehling's solution.

[1] From the Clinical Laboratory of the College of Physicians and Surgeons.

[2] This apparatus can be obtained through Eimer & Amend, of New York, who are authorized manufacturers.

After the steps are carried out as directed above the last tube showing incomplete reduction is noted, and the remaining tubes containing a smaller quantity of urine are brought up to the same amount by the further addition. The urine is now diluted with three volumes of water, and after 1/20 c.c., which represents 1/80 c.c. of urine, is added to No. 1, 2/80 to No. 2, etc., proceed with the test as before. The number of eighths c.c. of urine required to complete the reduction are added to the amount already used and the calculation made accordingly. The result will give the exact per cent. of sugar present.

Example.—If the last tube, showing a bluish tint, contains 6/20 c.c. of urine and 3/80 c.c. more are added before the color entirely disappears, the equation is as follows:

$$6/20 + 3/80 + 27/80$$
$$27 : \quad 80 :: \quad .01 : \times$$
$$\times = .0292 +$$
$$1 : .0292 + :: 100 : \times$$
$$\times = 2.92 + \text{ per cent. of sugar.}$$

The following advantages are claimed by the author for this method: (1) The estimation can ordinarily be made in less than ten minutes, which is less than half the time required by the original Fehling's method. (2) With reasonable care the results obtained are decidedly more accurate. (3) By means of the number of tubes, several can be used for control tests; thus one can make two or more determinations at the same time. (4) The solution never reaching the boiling temperature, the possibility of substances appearing in the urine which reduce Fehling's solution at the boiling point, as uric acid, kreatin, kreatinin, nucleoalbumin, etc., is eliminated. (5) The delicacy of the test is not impaired by removing some of the solution for the purpose of determining the end-reaction. (6) In the event too much urine is added to one tube the estimation can be carried out in the other tubes, thereby obviating the necessity of repeating the whole process.

PRESENT-DAY TREATMENT OF TUBERCULOSIS.[1]

BY J. W. KIME, M.D.,
OF FORT DODGE, IOWA;
SUPERINTENDENT OF BOULDER LODGE SANATORIUM FOR TUBERCULOSIS.

WHEN a diagnosis of tuberculosis has been made the question of treatment at once presents itself, "What shall be done with the patient?" Almost without a dissenting voice, either from physician or laity, comes the answer, "Change climate at once; go to Colorado, Arizona, New Mexico, Southern California, Florida or North Carolina."

Why?

We have here presented the most varied climes, the widest ranges of temperature, the greatest diversity of humidity, and altitudes extending from the sea level to that of the snow-capped mountains in the heart of the continent.

[1] Read before the Iowa State Medical Society, May 20, 1904.

The cases are the same, their circumstances the same and the ability of their advisers the same. Why, then, opinions of so great diversity? It is unusual in the practice of medicine that the experience of one physician is diametrically opposed to that of another of equal ability. Neither is it here. Cases get well in all climates, in all altitudes, in all degrees of humidity and without any regard whatever to the degree of temperature. And, conversely, new cases arise in all climes, in persons who have never changed residence and without any regard to climatic conditions.

A study of the various health resorts States referred to shows the following:

	Altitude.	Barometric Pressure.	Percentage of Sunshine.	Humidity. 8 A.M.	8 P.M.	Mean.	Temperature. Spring.	Summer.	Fall.	Winter.	Average.
Asheville	2,250	....	65	..	..	76	54	71	55	38	55
Denver	5,291	24.72	72	61	39	50	47	69	50	31	49
Jacksonville	43	30.03	59	85	77	81	68	81	70	56	69
Los Angeles	338	29.62	73	78	64	71	50	68	63	54	61
Phoenix	1,108	28.75	84	50	24	37	67	87	69	52	69
Santa Fé	7,013	23.27	77	57	36	46	47	66	49	31	48
Des Moines	861	29.11	59	80	65	72	48	72	50	23	48

The above data have been kindly furnished me by Dr. Geo. M. Chappel, director of the Iowa Weather Service.

Since each of these widely differing climates shows results in a certain percentage of recoveries, and none of them excels to any appreciable extent over others, it is evident that neither temperature, humidity, elevation, atmospheric pressure or percentage of sunshine is the factor to which the favorable change may be accredited.

There is no marked difference in the number of recoveries, whether in Norway, the British Isles, in Germany, France or Italy. Crossing to our own side of the Atlantic we find like results in Massachusetts near the sea level, in the Adirondacks of New York, in Pennsylvania, in the Valley of the Mississippi, in the Rocky Mountain region and in the great Southwest. Equally good results are obtained on the mountain-top or at the sea level, in the dry and arid regions, or on board a vessel in the open sea. As between the invigorating breezes of the North and the depressing heat of the South the former are much to be preferred. In New York or Massachusetts, in Wisconsin or in Iowa patients under proper supervision will do infinitely better, and more of them will get well than if they seek some fabled clime in some far-off land.

The benefits to be derived from a change of climate are nothing to be compared to the hardships sustained, to the wide separation from home and friends and the weary waitings for the return to health. All writers agree that this is not a question of months, but of years, and more recently it is affirmed that the change must be a permanent one. As a result of the extravagant claims of climatologists, some of the sections named have been flooded with poor consumptives, many too sick to be on their feet, with money

gone and friends thousands of miles away. Even for those with means and in fair physical condition it is daily becoming more difficult to find suitable shelter. Few doors are open to them. In Denver and in many other places I find that children, dogs and consumptives are classed together as undesirable tenants. California proposes legislation to keep the consumptive out. In all the sections noted, except possibly Asheville, N. C., there is not a single sanatorium of any size that is open to these patients.

Such a place was promised at Idyllwild, in Southern California, but it has become a pleasure resort, and consumptives are no longer admitted. There are a few tent colonies and some small private institutions, but nothing worthy of comparison with the sanatoria in New England and in the Eastern States, sections not noted for their climatic conditions. None of these health resort States are prepared to care properly for the tuberculous patient, and it is little short of homicide to send him where no preparation has been made for his reception. There is so little in specific climate that it may practically be ignored without detriment to the patient. Were figures necessary to confirm this statement they might be found in your own case records. Of all those sent but few are now alive.

In referring patients to any climate the order is simply, "Go." Not a word of what to do or how to live, of life in the open air all the time, of special diet and forced feeding, of rest and constant medical supervision. All this is left to the patient's own sweet will. And the consumptive patient has no will. Tuberculosis is to a marked degree a species of insanity—insanity in the sense that the mind of such a patient is no longer a normal mind. The toxins secreted so affect the delicate mechanism which has for its function the transformation of the material cell into the intangible and immaterial thing which we call "mind" that the normal flow of cerebration is interrupted, and the patient is controlled by moods and spells that do not characterize his actual self. Yet this patient, sick both in body and in mind, is given rein to drift with every passing whim in any direction that resistance does not present. Little wonder is it indeed that he falls a prey to all the fakes and charlatanry of the day, that all the nostrums are tried and all the cures are taken!

It is unquestioned by all who are qualified to express an opinion, that the physician who advises a change of climate for the cure of tuberculosis does his patient a grave injustice, he reveals his inacquaintance with the modern treatment of the disease and stands at least half a decade behind the onward progress of the profession in which he is enrolled.

Climate in tuberculosis is a will-o'-the-wisp, it is the end of the rainbow with its pot of gold. It is ever just a little beyond. It rests in Colorado, New Mexico, Arizona, California. Like children in their simple faith chasing the rainbow's vanishing end and delving for treasures where once it stood, our patient pursues his phantom till worn and wasted, weary but hopeful still, he falls asleep and wakes to learn that the magic end of the bow of promise rests upon the mystic shores of the spirit land.

It has repeatedly been shown that cure is seldom effected by climate to such an extent that the patient may return to his former home. That is, one cured in Colorado or California must remain in the climate where improvement was effected. All practitioners have noted this fact, and all phthisiologists assert its importance. These patients must be treated as near to their places of residence as may be possible, and fortunately, even the best climate is of secondary importance to methods at our command which are readily obtainable in any suitable locality. In other words, it is everywhere conceded by those in position to know best, that patients sent afar from home to some climatic resort are leaving conditions better suited to their recovery and, with all the added hardships, are not receiving the benefits that might be found near home.

The exaggerated claims for climate in the past have been reduced to the single one that that climate is best which permits the greatest number of hours to be passed in the open air.

In all tuberculosis sanatoria, both in Europe and America, no matter where located, it is found entirely practical to keep patients in the open air not less than twenty hours out of the twenty-four. This is likewise true for Iowa. Little inconvenience is found in the open air method, both day and night, except on the very few days when the mercury ranges far below zero.

The excessively cold weather of January and February of this year will be remembered. For an entire month the mercury scarcely rose to the zero point, while the frost penetrated to a depth of six feet or more into the ground. Yet during all this period, with the exception of a very few days when the lowest points were touched, every patient at Fort Dodge was in the open air both day and night, except at meal times. Not only this, but the patients were perfectly comfortable and contented. Nor do these conditions apply to Iowa alone; they are known to be true for all that vast region extending from Maine to Iowa, and it is difficult to conceive a climate that will permit a greater number of hours to be passed in the open air.

The open-air method may be variously applied during the winter months in our northern climate. Trudeau and Loomis Sanatorium place their patients on open porches well protected from the winds. Many institutions abroad adopt the same measures.

We have found it very convenient to practically convert the patient's room into an open porch by throwing the windows, which are of large dimensions, wide open, while on the opposite side of each room ventilating shafts pass upward through the roof. The patients are kept comfortable by means of clothing, robes, caps, foot-warmers, etc.

So important is the correct expression of the present professional opinion upon this question

that I quote some of the best authorities. Trudeau says: "When I went to the Adirondacks in 1873 the medical profession took little interest in the disease known as consumption, there was no recognized treatment for it except change of climate, and patients were sent principally to warm climates in a desultory sort of way, because they coughed, and nothing that could be done for them at home was of any avail.

"Each medical authority held differing and often very decided views as to the relative advantages of various climates; some advising warmth and equability, others laying special stress on dryness or elevation. Nevertheless little by little it became evident that the great majority of consumptives died wherever they went, and the few recoveries that took place occurred in regions which differed widely as to elevation, temperature and dryness, and that as many patients recovered in the intense cold and storms of the high Alps and other mountains as in the warm, equable temperature and dryness of atmosphere to be found in such countries as Egypt and the south of France, while cures were reported from time to time in patients who had gone on long sea voyages or remained in indifferent climates where none of the conditions considered essential existed.

"Wherever the consumptive was sent by his physician, little or no stress was laid upon regulating the habits of his daily life, beyond a recommendation to live out-of-doors and to exercise as much as possible, while for medication cod-liver oil and, later, creosote were generally prescribed."

I regret to say that in Iowa, as far as this question is concerned, a very large percentage of physicians are still living in the year A.D. 1873.

Knopf says: "There is still a vast diversity of opinion as to the respective merits of what are still sometimes called "specific climates" for consumptives; but the number of phthisio-therapeutists who consider even the best and most suitable climate of secondary importance, and the hygienic and dietetic treatment, preferably in a closed establishment, or under constant medical supervision in congenial surroundings, the all-important factor, is constantly increasing."

Hillier, a well-known English authority, says: "Ocean voyages, high altitudes and dry climates have all been eulogized in turn as remedies for phthisis. I have had phthisical patients under my care and observation for considerable periods of time under all these conditions, and the conclusion I have come to is that the benefit derived in every case is chiefly dependent on the extent to which the patient is constantly kept in pure air."

As long ago as 1897 an Iowa physician, after spending several years in Southern California, New Mexico and Arizona, said: "One hundred men buy lottery tickets, one receives a prize. The ninety-nine have not only received blanks, but they have sustained heavy losses. The successful one's name is heralded to the world and soon all know of his gain. The ninety-nine welcome seclusion. A few itinerant consumptives are perhaps to-day enjoying recovered strength and health, while thousands have sacrificed their only chance of recovery in their mad search in many climes for that which they might have found at home, if their wisdom had been as ardent as their zeal."

Medicines.—The medical history of a case of tuberculosis usually is: (1) A course of patent medicines prescribed by himself, the druggist, or by the patient's friends. (2) A course of medicine under the physician, consisting of creosote, guaiacol, cod-lived oil, maltine, tonics, etc. (3) A course of tuberculin, lymph, copper, or other specific for revenue only. It is difficult to say which of these courses is most harmful to the patient. All lull him into an unsuspecting belief that something is being done, and that he is getting better, while daily his chances for recovery are slipping away from him.

While it is certain that no medicine or lymph or other substance has any known value whatever on the tuberculous process, drugs have a legitimate place in this disease. Intercurrent symptoms arise and occasionally call for treatment. If the cough is excessive, night-sweats severe, diarrhea exhausting, or other like troubles arise, remedies suitable for their relief are indicated. But that permanent relief may come from drugs is an error no less grave than that the principles of Christian Science applied might be fraught with results for good. Time is lost in any attempt to treat these cases with medicines, and time is the essential factor which determines the chances of recovery in this disease.

In this connection I quote from the report of "The Tuberculosis Committee of the Charity Organization Society of the City of New York," a committee composed of many of the best phthisiologists in this country. It says:

"*Resolved*, That a public announcement be made that it is the unanimous opinion of the members of this committee that there exists no specific medicine for the treatment of pulmonary tuberculosis, and that no cure can be expected from any kind of medicine or method except the regularly accepted treatment, which relies mainly upon pure air and nourishing food."

What then shall we do with the consumptive patient?

First, we must recognize him much earlier than has been done by many in the past. It is not unusual to see these patients in almost their final stages without a diagnosis having been made. Practically all such cases die, no matter where they go or what they do. It is exceedingly important that they be recognized in their incipient stages. Time must not be lost in their treatment with medicines. These do no good, while each day the patient approaches nearer to that point when recovery is impossible.

Of all the factors in the treatment of tuberculosis fresh air and sunshine stand first. Trudeau puts it, fresh air and sunshine 50 per cent., nutritious diet 25 per cent., rest 25 per cent.

Medical supervision, constant, painstaking, and with the firmness of military discipline, is necessary to carry out the conditions essential to the proper treatment of this disease. This may be found only in the modern sanatorium for tuberculosis, a full discussion of which time will not now permit.

MEDICAL PROGRESS.

SURGERY.

Ascaridiasis of the Liver and Pancreas.—About one year ago post-mortem observation confirmed the diagnosis of a case of ascaridiasis of the biliary passages and the liver, as well as of the duct of Wirsung and the pancreas, made by O. VIERORDT (*Samml. klinisch. Vorträge*, June, 1904). This was the first instance in which this condition had been diagnosed. The case was that of a two-year-old child, in whom the family and past history had been negative. During the summer the child appeared ill, without any special symptoms except a slight jaundice. After several days of apparent malaise, in the latter part of September, while at the table he began to vomit. The material brought up contained three worms. Following this was a fever of 101.3° to 102.2° F. of three days' duration. After a course of santonin he passed, two days later, per anum, 64 worms, and every day thereafter from 12 to 15 worms. The vomiting occurred on September 27, and three days later there occurred severe abdominal pains. For eight to ten days there was cough, marked emaciation, weakness and complete anorexia. There was absence of fever from the end of September until October 20, when it reappeared. There were four to five daily stools, pulpy, frequently green and slimy. On admission to the hospital on October 22 the child was quite sick. The abdomen was slightly swollen, and the hypochondriac region was tender on pressure. The lower border of the liver in the mammillary line was two finger-breadths below the free border of the ribs. The upper border of the liver was normal and the spleen not distinctly enlarged. The urine showed a faintly positive iron-chloride reaction, and contained neither aceton, albumin nor sugar. There was no leucocytosis or eosinophilia. Examination of the worms passed showed them to be of the genus and species *Ascaris lumbricoides*. A presumptive diagnosis of ascaridiasis of the liver was made. The course of the disease was as follows: A remittent and intermittent fever, with apices at 104° F., without chills or noticeable sweating, and with a gradual fall; considerable pain in the upper part of the abdomen and great restlessness. On October 26, examination of the urine showed a trace of albumin. For two weeks the clinical picture did not change. The right lobe of the liver was distinctly enlarged, hard, sensitive and with a sharp inferior border. A tumor-like enlargement of the edge of the left lobe was indistinctly made out. Under narcosis the spleen was quite palpable. At times, in the left hypochondrium, between the umbilicus and the upper border of the spleen, there was detected a tumor, not sharply circumscribed, round and movable on pressure and then completely disappearing. Worms appeared daily in the stools. The entire clinical picture bespoke with greatest probability ascaris-abscesses of the liver, as well as ascaridiasis of the biliary passages. The movable tumor in the left hypochondrium suggested an ascaris-abscess of the tail of the pancreas. The failure of anthelmintic remedies and the progressive decline, together with the multiplicity of abscesses, made a surgical operation imperative. An incision 7 cm. long was made one finger's-breadth below the free border of the ribs. The upper surface of the liver presented two furuncle-like prominences. The under surface of the left lobe presented a soft, fluctuating spot. The liver was sewed to the edges of the wound. Three days later a second operation was performed and provisional punctures of the liver made. The result of the latter brought only blood, no pus or worms. No further operative procedures were performed. At no time did jaundice appear. Death occurred on November 20 from exhaustion. The autopsy revealed ascarides in the intestine, esophagus and larynx (in the latter probably post-mortal), in the ductus choledochus and in the hepatic ducts, which were enormously dilated and occluded with worms; in the intrahepatic biliary passages, which were also dilated and surrounded by necrotic liver-substance, containing partly a necrotic, pulpy mass, and partly worms. The same conditions prevailed in the pancreas.

Hemoglobin Estimation with Tallqvist Scale.—D. ZUR VERTH and D. SCHUMACHER (*Münch. med. Woch.*, July 26, 1904) have used the Tallqvist scale in all their cases and have controlled the results with the Fleischl instrument. In a hundred cases differences up to 15 per cent. were noticed five times; 10 per cent., 34 times; 5 per cent., 42 times., and no difference, 19 times. The estimation was too high or too low in an equal number. The greatest variation was always noted with blood rich in hemoglobin; in anemia, where the accurate estimation is of most value, fairly constant figures were obtained. The scale is therefore highly recommended in office practice.

Treatment of Post-operative Peritonitis.—In considering instances of peritonitis which develop after operation, E. H. GRANDIN (*Am. Jour. Obst.*, July, 1904) differentiates three types: the *paretic, inflammatory* and *septic*. The first class consists of cases in which, after abdominal section, there is a gradual development of tympanites, the stomach rejects food and drugs, and there is an elevation of pulse and temperature. The treatment recommended is full hypodermic doses of atropine or hyoscine hydrobromate to relax the spasm of the bowel. The *inflammatory* type is characterized by a concomitant rise of temperature, pulse and respiration, three to four days after operation. The bowels may or may not respond, the stomach is usually intolerant to food and medication. Such conditions call for rest, an ice-bag should be placed on the abdomen, the stomach washed out and food administered by rectum. To give rest to the inflamed peritoneal surfaces, codeine is the best drug since it does not paralyze peristalsis or upset the stomach. The *septic* form is characterized by rapid pulse and respiration and *low* temperature. The belly may or may not be tympanitic, the kidneys are inclined to be torpid, the stomach apt to be intolerant and the bowels loose. In this condition a generalized toxemia must be dealt with and a sustaining treatment instituted by the discriminating use of alcohol, strychnine and digitalis. Pus should always be attacked under the recognized rules of surgery.

MEDICINE.

Embolism and Thrombosis of the Mesenteric Vessels.—The typical symptoms of embolism of the superior mesenteric vessels are sudden, very severe, colicky pains in the abdomen, fall of temperature, intestinal hemorrhage, tympanites and exudation into the peritoneal cavity, with signs of peritonitis. K. OSSWALD (*Deutsch. Zeitsch. f. klin. Med.*, Vol. 53) points out, however, that hemorrhages are frequently absent, and that all the

symptoms may point to a paralytic ileus. The cause of the vascular obstruction is usually an embolus in the pulmonary veins, the left heart or the aorta, owing to endocarditis, atheroma or aneurism, but occasionally there is only a local thrombus. The presence of other emboli forms a valuable guide for diagnosis. In the presence of intestinal hemorrhage one must rule out ulcers and portal obstruction, such as occurs in cirrhosis, hepatic syphilis, old adhesions about the porta hepatis, cachexia and marasmus. Where there is intestinal obstruction the differential diagnosis must consider volvulus, invagination and acute peritonitis. The clinical symptoms of embolism of the artery and thrombosis of the vein are exactly alike; the latter condition may be secondary from portal thrombosis, or primary and ascending from the intestines; enteritis, with or without fever, may precede, and varices and hemorrhoids are often present. In the author's case the patient lived only four hours after the artery became obstructed, and at autopsy the vein was also found thrombosed. The cause of the embolus was atheroma of the aorta, of the thrombosis, an enteritis, aided by the arterial occlusion. In a second case the course was more protracted, since many of the smaller peripheral vessels had become obstructed. In treating cases of embolism it is very difficult to decide if an operation is indicated or if the heart's action should be stimulated. The author believes that medical treatment alone should be resorted to as long as there is no intestinal obstruction, but with the latter, an operation alone will save the patient. In doubtful cases, surgical interference should also be considered.

Rare Complications of Dysentery.—The complications of dysentery differ with the two forms, amebic and bacillary. In the former liver abscess is most frequent and perforative peritonitis, profuse intestinal hemorrhage, stenosis of the intestines, pulmonary or cerebral abscess and paraplegia may occur, while in the latter the most frequent complications are inflammation of the joints, tendon-sheaths and serous membranes, and, rarely, parotitis. A patient under the care of B. MARKWALD (*Deutsch. Zeitsch. f. klin. Med.*, Vol. 53) was suffering from the bacillary form and developed a urethritis and double conjunctivitis, with severe iridocyclitis, during the course of his disease. The former manifested itself in pain along the canal, with swollen orifice and slight mucoid secretion. In both secretion of the urethra and the conjunctivæ, bacilli were found, and the patient's blood strongly agglutinated the Shiga type.

Menstrual Jaundice.—A patient under the observation of L. METZGER (*Zeitsch. f. klin. Med.*, Vol. 53) presented all the symptoms of severe liver disease. An operation was postponed, since she was menstruating, and when seen a few days later, the jaundice and other symptoms had disappeared completely. With every menstruation, however, the attack was repeated, so that a close relation between the two could not be denied. The author believes that in some individuals, menstruation is accompanied by a contraction of the biliary passages, which permits the bile to pass into the lymphatics instead of the gall-bladder.

Polymyositis.—The patient observed by W. STRENG (*Zeitsch. f. klin. Med.*, Vol. 53) suffered from severe pains in the muscles of the extremities, with tenderness, a dry dermatitis, edema of the eyelids and of the arms and swelling of the mucous membrane of the mouth. The patient was first treated for rheumatism, but when the inflammation became worse and extended to nearly every muscle of the body, a piece was excised for microscopical examination. The muscle fibers were almost entirely destroyed, and the interstitial connective tissue presented a marked proliferation of round cells. The patient soon developed paralysis of the muscles of deglutition and died of pneumonia. At autopsy almost all the muscles, including the diaphragm, were affected. Not all cases are fatal; indeed, the author believes that many patients are wrongly treated for muscular rheumatism.

Theocin Poisoning.—Theocin has such pronounced diuretic properties, that it is coming more and more into favor, especially in cardiac cases with edema. In a series of cases, E. ALLARD (*Deutsch. Arch. f. klin. Med.*, Vol. 80, Nos. 5 and 6) has, however, observed very severe epileptiform convulsions which were directly responsible for death. At autopsy, the mucous membrane of the stomach was ulcerated and infiltrated with blood, though the dose employed had not been excessive. Experiments with animals then convinced the author that lesions of the stomach are a common consequence of medicinal doses, hence great caution should be exercised. Many of the organs also gave evidence of cloudy swelling.

Fibrinous Bronchitis.—In order to determine the nature of the coagula coughed up in fibrinous bronchitis, the chemical analysis gives better results than the microscopical, but where insufficient material is at hand, it should always be hardened and stained. G. LIEBERMEISTER (*Deutsch. Arch. f. klin. Med.*, Vol. 80, Nos. 5 and 6) uses the thionin and mucicarmine stains to identify mucus, and Kockel's method for fibrin, since Weigert's is less liable where both fibrin and mucous are together. In the majority of cases of fibrinous bronchitis examined, the clots consisted chiefly of fibrin, but in 7 out of 13, mucin was also present. Curshmann's spirals were only found once, and the hunt for Charcot-Leyden crystals and eosinophile cells was always negative.

Cheyne-Stokes Breathing in Diabetes.—A characteristic large type of breathing has been described as typical for diabetes mellitus, and sometimes it is possible to diagnose the approach of coma, since this breathing may precede the latter for several hours, though the subjective complaints of the patients may be slight. W. EBSTEIN (*Deutsch. Arch. f. klin. Med.*, Vol. 50, Nos. 5 and 6) cites several cases where the coma was not accompanied by Kussmaul's breathing, but by a typical Cheyne-Stokes or an irregular type. He has also seen cases of chronic nephritis with the diabetic type of respiration, and argues that both forms are closely allied and probably have the same physiological cause.

Bence-Jones Albuminuria.—According to the latest views, Bence-Jones bodies occur in the urine exclusively in multiple tumors of the skeleton. They need not necessarily be myelomata, but may belong to the class of sarcomata, lymphosarcomata, chondrosarcomata or endotheliomata. A few cases are on record where a clinical diagnosis of the osteomalacia was made, but a microscopical examination always disclosed a tumor. F. VOIT and H. SALVEND (*Münch. med. Woch.*, July 19, 1904) describe in detail the urinary examination of their patient, who gave no symptoms of bone-affection. The urine was atypical in that a precipitate only formed on cooling a sample that had been boiled with acetic acid. On again heating, the precipitate dissolved, to reprecipitate on cooling. A quantitative estimation was possible after the addition of acetate of iron, ammonium sulphate or alcohol. The freshly-precipitated body was readily soluble in water, but lost this property if permitted to stand under alcohol for some time. The urine was also peculiar in that it showed very little tendency to decompose, but after three or four days the albumin began to separate out. The solubility and precipitation can be modified considerably by altering the proportion of salts

in the urine or by adding acid. Frequently another proteid accompanies the Bence-Jones albumin, which seems to belong more to the globulins. The origin of these bodies is still obscure; it is not likely that they are formed within the tumors themselves, as they are often excreted in too large amounts. By giving the patients more albumin, a larger quantity will also appear in the urine, hence the tumor-cells probably in some way attack and modify the circulating proteid. Another interesting contribution to the subject of bone-tumors is contained in the article of S. JELLINEK (*Virchow's Archiv*, Vol. 177, No. 1). Although the patient has sustained many pathological fractures during life, and his skeleton was literally riddled with tumors, Bence-Jones bodies could never be found in the urine. Microscopically the tumors were myelomata.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Reaction of Protoplasms of Chemotaxis.—This paper is the eighty-sixth report of the Scientific Grants Committee of the British Medical Association. It is interesting to note that presumably on account of the activity of the antivivisection powers in England, the research student J. O. WAKELIN BARRATT publishes as a report (*Brit. Med. Jour.*, June 18, 1904) from the physiological Institute at Göttingen. His summary is as follows: (1) Exposure of *Paramœcia* to acids or alkalies of concentration sufficient to kill in twenty to thirty minutes does not affect the staining reaction of the organisms; (2) prolonged exposure of *Paramœcia* to acids or alkalies of higher concentration causes the well known appearance of "accentuation of basic and acid staining," respectively, but this is a change affecting the protoplasm after death, and therefore of a different order from that occurring in relation to chemiotactic phenomena; (3) *Paramœcia* killed by the constant current resemble *Paramœcia* killed by acids and alkalies of minimum lethal concentration in respect of the absence of any alteration of staining reaction; (4) the chemical reaction of the protoplasm of *Paramœcia* cannot be determined by means of indicators in respect of a concentration of H plus and OH minus ions, which is less than 0.001 N. Within this limit, the protoplasm, living or dead, gives no evidence of acid or alkaline reaction; (5) the protoplasm of *Paramœcia* killed by mineral acids or by alkalies of low concentration gives no evidence of acid or alkaline reaction with methylorange or phenolphthalein; (6) *Paramœcia* killed by the constant current do not exhibit any acid or alkaline reaction.

Infective Element in Gout.—Those who suffer most keenly from certain diseases are not always the most patient and successful observers of the lesion. This is not the case with the English in their studies of gout. CHALMERS WATSON (*Brit. Med. Jour.*, July 16, 1904) presents a series of remarkably interesting microphotographs which illustrate many points on the pathology of gouty tissues. They support the views of Garrod, who, discussing the occurrence of fat in the bone-marrow of gouty individuals, states:

"Although I have not quantitatively determined the amount of fat in the bones of patients who have died from aggravated forms of gout, I am convinced that it often exists in large quantities; whether this is related to the disease or is dependent on imperfect nutrition is not known. It has been held by Ebstein that bone-marrow took an essential part in the development of primary gout—his belief being that the marrow is a site of production of uric acid. The author agrees with Ebstein in his views on the important part played by the bone-marrow in gout, but he goes further in suggesting that it is of no greater importance than the bone-marrow in all infectious diseases. The clinical picture of acute gout is, typically, that of an acute infection; the onset, the chart, the local conditions, the relapses all suggest it. Furthermore the white cells undergo a striking and remarkable change. The interpretation of this change is not clear, but it suggests to the author the existence of infection. Furthermore, the study of gout from a comparative standpoint—it is often seen in fowls—affords ground for a similar belief.

Observations in Sarcoma.—Carefully recorded clinical studies have advanced the subject of sarcoma fully as much, if not more, than laboratory observations. ANDREW J. MCCOSH (*Annals of Surgery*, August, 1904) presents his records of 125 cases of sarcoma. In each one the diagnosis was verified by pathological microscopical study. Twenty-seven of the total number were lost sight of, leaving 98. These were all studied in greater or less detail. Perhaps the most interesting result arrived at by the author is that the greatest number of cases occurred between the ages of thirty and forty years. This, as he says, is by no means in accord with the prevailing idea that sarcoma develops mainly in young adults. He concludes, then, that scarcomata develop in adult life rather than in adolescence.

As to sex, the author's tables show them to be very evenly divided. Of the 98 under observation, 51 have died of metastasis or recurrence, a little over 50 per cent. McCosh discusses the frequency with which a myoma is transformed into a sarcoma, and concludes that this direct metaplasia of the smooth muscle cells into sarcomatous cells is generally recognized.

The average duration of life of the 51 operated patients, who subsequently died, was twenty-five months, the maximum being ninety-six months and the minimum four months. Of the remainder, some are in process of dying, while others are too recently operated on to be counted. This leaves, of the 98 patients, but 39 who have survived the operation for one year or longer. Of the 98 patients, in 56 the operation was complete. Of the remaining 42 incomplete sections one resulted in a cure. Of the 56 complete operations, 14 patients have died of recurrence or metastasis. Of nine lymphosarcomata operated upon, all died—this agreeing with the results of other surgeons. In discussing sarcomata of the lower extremity, McCosh dwells interestingly on Mikulicz's protestation that encapsulated grant-cell sarcomata should be resected instead of amputating the extremity. He holds that while many good results have sprung from resection, he has never seen a case whose interests could be best served by resection. He further discusses the question of amputation and disarticulation, and states that in his opinion the lesser operation is "often preferable and equally safe."

PHYSIOLOGY.

Influence of Ligation of the Extremities on Blood-pressure.—The tying-off of extremities so that the return flow of venous blood is interfered with while the arteries are not compressed, is a procedure which has been employed in pulmonary hemorrhage, since less blood is in circulation, and the general arterial pressure will fall. Esmarch's method is the converse of this; it consists of forcing out the blood of the extremities into the general circulation, and has been used after severe puerperal hemorrhages, though it may be followed by gangrene or pulmonary embolism. W. PLASKUDA (*Deutsch. Arch. f. klin. Med.*, Vol. 80, Nos. 5 and 6) finds that by tying off the extremities by means of a rubber bandage, three-fourths to five-fourths of a liter of blood can be abstracted from the head or trunk. Stasis

in three extremities will diminish the blood-pressure 20 millimeters of mercury (about 14 per cent.). In nervous individuals this is not, however, so constant. Occasionally there will be a sudden drop, with symptoms of collapse, which disappear rapidly if the bandage is removed. If the blood is forced out of the extremities the pressure will rise, but this depends more on nervous than mechanical influences.

The Nature of Chemical and Electrical Stimulation.—Those who are interested in rational pharmacology will find much that is valuable in recent physiological researches in the nature of stimulation. A. P. Matthews (*Am. Jour. of Physiol.*, August 1, 1904), who has done considerable work in the investigation of the relation between ions and physiological phenomena, has conducted a research, the result of which shows that the physiological action of an ion depends upon its electrical state and its electrical stability. He based his experiments upon the well-known fact that the chemical properties of an element vary with its electrical state; thus, iodine in sodium iodide has different chemical properties from iodine itself; nascent (negative) hydrogen reduces, while positive hydrogen oxidizes. Since the chemical nature of a substance depends upon its electrical condition, the conclusion is drawn that its physiological or pharmacological action will also depend on the same factor. As evidence of the truth of this conclusion the following examples are cited: Ferric salts are poisonous to *Fundulus* embryos in concentration, while ferrous salts require a concentration of to kill in the same time, the difference between these salts being the electrical state of the iron. The author's paper adduces further proof of the above proposition and also the fact that not only do the atoms change their actions with their electrical state, but that they act by means of their electrical condition or their electrical charges; and that positively and negatively charged ions have opposite actions. All ions of the same sign act alike, differing in the degree of their action, because the ease with which they change their electrical condition, or give up their charges, varies. This latter factor is measured by the solution tension. The facts of chemical stimulation are summarized as follows: Nearly all electrolytes and non-electrolytes will stimulate the sciatic nerve of the frog in solutions having an osmotic pressure of about 14 atmospheres. This stimulation is not due to the electrical condition of the solution, since it is common to electrolytes as well as to non-electrolytes. It is not due wholly to the extraction of water increasing the concentration of salts in the outside of the nerve and setting up thereby a concentration chain, since the non-electrolytes stimulate nearly or quite as powerfully in such solutions as the electrolytes. This stimulation is probably due to the extraction of water setting up a definite change in the colloids of the nerve rendering the protoplasmic hydrosol unstable. Many electrolytes stimulate in solutions which are so dilute as not to extract water. This stimulation is due to the electrical condition of the solution. All anions have a stimulating action; all cations, a depressing action. This is shown by the facts adduced, as well as by the well-known phenomena of electrical stimulation, in which the opposite electrodes have opposite actions. The ions are minute, freely moving electrodes of different voltages. The physiological action of any ion depends (1) in its concentration; (2) on the sign of its electrical charge; (3) on its electrical stability or ionic potential. Its action is also modified by its velocity and weight; the faster it moves, the more powerful it is; the heavier it is, the less powerful. Physiological action is hence dependent upon the electrical state and stability of the ion and is independent of chemical composition, except as the chemical composition may influence its velocity and weight. Whether any salt stimulates or depresses, depends upon the relative efficiency of its anion and cation. If the anion markedly predominates, as in hydrates, the salt stimulates; if the cation predominates, the salt depresses. Chemical stimulation is thus shown to be electrical and dependent upon the electrical charges of the ions. Electrical stimulation is produced by modifying the distribution of ions in the nerve and thus altering their concentration.

OBSTETRICS AND GYNECOLOGY.

Etiology of Kraurosis Vulvæ.—Certain histological conditions, which are apparently characteristic for this disease, are described by P. Jung (*Zeitsch. f. Geb. und Gyn.*, Vol. 52, No. 1). These consist of infiltration of small cells, hyperemia, edema, loss of elastic fibers and partial sclerosis of the connective tissue of the corium. In some of these cases there was no symptom of kraurosis and macroscopically no contraction or discoloration of the tissues could be detected. The histological difference between a well-marked case of kraurosis and a chronic vulvitis, is not qualitative, but quantitative, and for this reason the author claims that the disease can no longer be looked upon as an entity, but must be considered as the terminal stage of a chronic vulvitis. The causes which underlie these conditions are: pruritus, chronic vaginal discharge of a specific or non-specific character, diabetes, syphilis, masturbation and neoplasms.

Determination of the Length of Pregnancy.—The many efforts which have been made to determine in advance the day on which the pregnancy in any given case will be terminated and labor begin, have never as yet resulted in anything which can be considered of practical value. F. Schatz (*Archiv f. Gyn.*, Vol. 72), has made a special study of this subject and believes that one of the most reliable means is afforded by the periodically recurring pains. In many instances, however, these are not felt and therefore pass unnoticed, but as a substitute the changes in arterial pressure, which run parallel with the menstrual periods, may be observed. The pains generally correspond in their rhythm with the periodic minimum and maximum of the blood pressure. When the maximum blood pressure and the period uterine contractions correspond, the day of expected labor may be quite definitely ascertained. This correspondence also explains what are often designated as early or late births. The number of months remains the same but their individual length varies and this causes an apparent variation in the length of the pregnancy. The author believes that the physiological month exists in reality, and not only in the form of the menstrual period, but is also marked by the recurring pains in pregnancy. It is marked by the variations in arterial pressure and also in other bodily functions.

Primary Hydatid of the Fallopian Tube.—The female pelvic organs are but rarely the localities chosen for the deposition and development of the ova of the *Tænia echinococcus*. They not uncommonly become involved in extensive hydatid growth development in the liver or other abdominal organs, but they are rarely the localities primarily affected. The ovary and the Fallopian tubes are among the last sites in the whole body selected by these parasites. So, for this reason, T. W. Eden (*Brit. Jour. of Obst.*, July, 1904), reports the following case: Mrs. E., aged forty years, was admitted to the Chelsea Hospital, London, complaining of pain in small of back and in the left side. Menstruation was regular but accompanied by pain during the whole period, in the hypogastric and sacral regions. She had

never been pregnant. Local examination showed a small, tense cyst in the pouch of Douglas, firmly adherent to the surrounding structures and connected by an easily palpated pedicle with the right cornua of the uterus. Dermoid cyst of the right ovary was the diagnosis. During the operation for its removal the cyst ruptured revealing the easily recognizable hydatid vesicles accompanied by lose membrane and a small amount of thin fluid. The tumor mass was carefully removed. No other masses could be discovered in the abdomen and the remaining viscera seemed to be free from hydatid disease. The Fallopian tube measured four inches from the divided end to the abdominal ostium. The inner third was not altered. With the upper border of the outer two-thirds was closely incorporated a cyst of considerable size; the tubal canal was intact, running apparently in the lower wall of the cyst. There was no communication whatever between the tubal canal and the cavity of the cyst. The cyst measured 4½ inches in vertical, 3 inches in transverse, and 2½ inches in anteroposterior diameter. It contained but a single cavity, the inner wall being smooth and polished, the hydatid membrane having been completely detached. The examination of the fluid showed large numbers of typical brood corpuscles, and free hooklets. The patient had lived all her life in London and had never kept a pet dog or cat or any other animal. The ova must have been taken in with some article of food.

The Electrothermic Angiotribe.—The idea of the angiotribe was originally suggested by Baker Brown in 1862. He, however, depended more on the element of heat than upon that of pressure. H. MACNAUGHTON JONES (*Lancet*, July 2, 1904), exhibited the Downes instrument before the meeting of the British Gynecological Society. He stated that Tate and Teith, as well as Byrne and Skene, had all depended more or less upon the application of these two principles for the control of hemorrhage. It was Skene who introduced the practice of electro-hemostasis. The advantages claimed for it are that there is no sloughing of the tissues, that it enables one to act upon a large surface including the lymphatics and opposing an obstacle to the spread of infection. Furthermore, as it leaves no bleeding surface behind it, the formation of adhesions is rendered less likely. Skene with his instrument did over 200 laparotomies without hemorrhage. He continued desiccation for from one-half to two minutes. Downes' improvement of Skene's instrument lay in the raising of the temperature to 212° F., the insuring of cool handles to the instrument and an increase in the degree of pressure. A maximum current of 60 amperes is necessary. The advantage of this is that the heat developed in the platinum causes the blades to heat more rapidly than with a lesser current, and there is less risk of burning out the platinum. Intestinal resection and anastomosis, in Downes' opinion, can by these instruments be made ideal.

THERAPEUTICS.

Active Principle of Suprarenal Tissue.—E. ABDERHALDEN and P. BERGELL (*Münch. med. Woch.*, June 7, 1904) have succeeded in obtaining the active substance of the suprarenal gland in chemically pure form. This epirenan forms pure white crystals which do not change color, even if kept in solution for months. A solution 1-1,200 to 1,300 corresponds in strength to a 1-1,000 solution of adrenalin or suprorenin. If a 1-1,200 solution is passed into the stomach of a dog, almost the entire amount can be recovered, showing that the vascular spasm in the stomach is so intense that hardly any absorption goes in. It would then be interesting to try epirenan in hemorrhage from gastric ulcers, etc.

Action of Salicylates on the Kidneys.—Careful urine examinations were made by E. KNECHT (*Münch. med. Woch.*, May 31, 1904) on patients who were receiving salicylates for rheumatism, but did not suffer from renal complication before treatment. That renal irritation may follow seems undoubted, but is hardly an argument against the use of salicylic acid for slight albuminuria with few casts were found in only seven out of forty cases. C. KLIENEBERG and R. OXENIUS (*Deutsch. Arch. f. klin. med.*, Vol. 80, Nos. 3 and 4) have studied the same question, and arrive at somewhat different conclusions. Albumin and casts are found in a surprisingly large number of normal individuals and patients suffering from rheumatism before they receive salicylates; after treatment the traces of albumin are more marked, the casts more numerous, and the epithelial cells very abundant, so that there is no doubt that a desquamative catarrh of the entire urogenital tract is set up in most cases. Even coarsely granular and waxy casts were occasionally encountered. A peculiar property of the nephritis is that it disappears even if large doses of salicylic acid are continued. Clinical symptoms of nephritis never appear, and in a patient already suffering from chronic nephritis, the albumin rapidly diminished with antirheumatic drugs, so that above observations possess more theoretical than practical value.

Lithiomercuric Iodide.—It has been generally assumed that the active radical of soluble mercuric salts is the mercurial, and that the higher the percentage of mercury, the more destructive the compound to bacteria. It has been shown, however, that mercuric iodide is fully three or four times as powerful in its effects on bacteria as corrosive sublimate, indicating that the combined iodine is as important a factor in the bactericidal action of the salt as the combined mercury. R. C. ROSENBERGER and J. W. ENGLAND (*Am. Med.*, June 25, 1904) have found that lithium iodide forms a compound with mercuric iodide which possesses features of superior value. It contains about 34 per cent. of mercury, 65 per cent. of iodine, and 1 per cent. of lithium. It is believed that it will decompose the alkaloidal toxins of micro-organisms more effectively than the other mercuric salts, and as it is not precipitated by fixed alkalies, the solution is not decomposed by the alkalies of the blood or the blood serum. A lesser quantity is required and hence there is less danger of mercurial poisoning. As regards the antiseptic action of the reagent, it was found that a 1—16,000 solution readily inhibited the *Bacillus coli, Bacillus pyocyaneus, Bacillus anthracis*, and *Streptococcus pyogenes* for twenty-four hours. The presence or absence of albumin made no difference.

Radium, Finsen Light and X-Ray.—These little understood agents are constantly before the questioning members of the profession. With all the work that has been done on them it is little short of wonderful that no progress has been made toward answering the problem as to how they do their work. C. M. O'BRIEN (*Brit. Med. Jour.*, July 23, 1904), considers that there is too little radium in the world to make its use a serious question, particularly in view of the fact that we have other agents which, to all appearance, do the work much better. He points to the very interesting sequence of events which began with the discovery by Koch in 1882 of the tubercle and, furthered by Finsen, Roentgen and Becquerel, ended in 1898 by the discovery of the Curiès. The unknowable "personal equation" which figures conspicuously in the therapy of all the radio-active agents is all important in the case of radium. He concludes with the statement that the combined use of X-ray and Finsen light affords the best chances of success.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 3, 1904.

WALTER REED AND THE PANAMA SANITARY OUTLOOK.

There are still many doubts in the minds of medical men, as well as the general public, concerning the early results of the American attempt to dig a canal at Panama. As to the ultimate success, of course, there is no possible hesitation; but the question is, How many lives is it going to cost, and is American control going to prove any more successful in solving the problems of sanitation and in reducing the enormous death-rate among the workmen which has proven the main obstacle in constructing the canal?

Malaria and yellow fever are two special sources of danger that must be avoided, if every foot of the canal is not to cost a human life. The problem then is whether our modern advance in the knowledge of the distribution of these and kindred diseases is sufficient to insure protection against them to such an extent as to make them at most passing visitants rather than enduring companions of the work across the Isthmus.

It seems that in a measure these problems have been solved, but the test of the solution on a large scale remains to be made. The attitude of sanitarians with regard to the precautions necessary to be taken is very different at the present time from what it would have been even five years ago. When the American occupation of Cuba was forced upon us it was thought that an improvement in the general sanitation of Havana would surely bring about a reduction in the death-rate from yellow fever. For the first year this seemed to be true, and while there was a reduction of more than one-half in the death-rate from all diseases, there was a distinct diminution also in the incidence of yellow fever, and one of the great menaces of the tropics seemed to be abolished. The next year, however, in spite of the most scrupulous municipal cleanliness and insistence on sanitary precautions of every kind, yellow fever raged with more virulence than for many years. More than half of the Governor-General's staff died from the disease, and Cubans were not slow to proclaim that yellow jack would prove too much for the Americans and all their sanitation.

Then came the splendid work of Walter Reed and his band of companions, and within a year the yellow fever problem was forever solved. The disease has not caused any alarm in Havana since, and for practically three years there have been no cases of the disease reported. This, too, notwithstanding the fact that when yellow fever is imported no special precautions are taken to avoid a contact with patients, and the only sanitary regulation is the absolute seclusion of the yellow fever sufferer from mosquitoes. As the result of this Cuban experience it can be said confidently that yellow fever at least will not play an important rôle in causing a high mortality among the laborers along the Panama Canal. What has been accomplished in Havana and elsewhere in Cuba, as well as in Porto Rico, can be done quite as effectually and with the promise of as much success in the canal zone, since the sanitary regulation of this territory is to be under the control of the men who have solved the problem in Cuba.

There remains malaria. This too, is a mosquito-borne disease, and as the result of the experience with yellow fever in Havana, not a little has been learned as to the possibility of reducing the incidence and mortality also of this possible cognate disease. Instead of the vague efforts at protection against this disease by the avoidance of the supposedly mephitic night air, by the consumption of quinine and whisky and care with regard to the possible malarial infection of the water supply, the prophylaxis of this disease has resolved itself into a set of very definite purposes.

Colonel William Gorgas, of the Medical Corps of the United States Army, who is to have charge of the Government's sanitary work in the Isthmus of Panama, has recently stated in the *Review of Reviews*, just what is to be attempted in order to prevent the spread of malaria. Most of the dwellers in the canal zone have had malaria, and many are sure to suffer from relapses. As the district abounds in mosquitoes the communication of the disease to foreign workmen who come in is sure to take place unless due restraint is placed on the mosquitoes. The whole effort of the sanitary corps will then be centralized on the single purpose of preventing mosquitoes from acquiring malaria from those already ill with the disease and then transferring it to those who have not as yet had it.

This will not be as difficult as might be thought, for it is proposed to organize, as in Panama, mosquito brigades in all the villages, whose work will be to destroy every possible breeding place of the mosquito and thus keep the number of the insects down to the lowest possible limit. Besides, all of the present population who have suffered from malaria are to be registered and the state of their health is to be the subject of regular inspection. Whenever they are suffering from a relapse of their malaria they are to be carefully protected from the possible approach of mosquitoes. This has been done with not a little success in Havana. It is believed from investigations already made in Panama that the yellow fever-bearing mosquito seldom wanders more than one hundred yards from the pool in which its antecedent larva was deposited and infected.

All this looks simple enough now. The very favorable outlook, however, is due entirely to the work of one man, Dr. Walter Reed, who, in his quiet, unassuming way, accomplished as much for medicine as did Jenner, Lister or Pasteur. His greatest monument will undoubtedly be the fact that the canal at Panama will be finished without the awful loss of life that would otherwise be unavoidable. It is only proper and befitting his position as an American medical man that another and more formal monument to him should proclaim to admiring countrymen how much the fellow members of his profession appreciate the work that was so successfully accomplished by this compatriot whose untimely death cut off one of the most distinguished physicians of his generation, but whose memory shall remain for all time as one of the glories of American medicine.

X-RAY TREATMENT OF LEUCEMIA.

While periods of marked and at times of long-continued improvement are not at all uncommon in the course of leucemia an actual arrest of the disease with complete recovery has thus far not been observed. Even in the remarkable case of the myeloid type, recently reported by Simon and Campbell (Medical News, July 23, 1904), in which, associated with great improvement of the patient's general condition, both the splenomegaly and the myelocytosis disappeared and have remained absent for over a year, it would hardly be warrantable to speak of a recovery. The writers themselves share this view. They state that "notwithstanding the general improvement and the disappearance of the splenomegaly and the myelocythemia there can scarcely be any doubt that the arrest of the disease is merely temporary, if indeed there is an arrest of the pathological process."

In view of the extremely grave prognosis, which the disease thus offers, with the older methods of treatment the results of recent investigations regarding the effect of the X-rays upon the progress of leucemia are most interesting and deserving of careful attention. The earlier reports dealing with the treatment of leucemia and allied conditions with the Roentgen rays have apparently been overlooked, and credit is usually given to Senn for its introduction. The right of priority, however, undoubtedly belongs to Pusey, whose first report appeared in the *Journal of the American Medical Association* of January 18 and April 12, 1902. Since then additional cases of leucemia treated in this manner have been recorded by Senn, Grad, Brown, Bryant and Crane, Grosh and Stone in the United States, by Krone and Ahrens in Germany and by Bozzolo in Italy. Altogether there are at present available data regarding the X-ray treatment of the disease in nine cases of the myeloid type and in three of the lymphadenoid variety. Barring the first of Pusey's cases, in which no success was had, distinct improvement is recorded in all the remaining cases. This has reference not only to the patient's general condition, but also to the splenomegaly and the blood changes. The improvement begins early and is progressive. That this is the direct result of the treatment can scarcely be doubted. In this respect the study of a single case is perhaps not altogether convincing, but a careful survey of the series certainly warrants the conclusion that in the X-rays the profession now has a definite means by which it can influence the

metabolism of lymphoid tissue. To judge from recent investigations of Heineke it appears, in fact, that the reaction on the part of the lymph follicles of the animal body to the X-rays is very much more delicate than that of the surface epithelium. For he could show that in dogs of medium size exposure of the abdomen to a hard tube at short range for fifteen minutes is sufficient to produce distinct nuclear fragmentation of the follicles of the spleen and the mesenteric lymph glands, which can be demonstrated after a few hours. Similar changes undoubtedly occur in the lymphadenoid structures of the leucemic patient as the result of the X-ray treatment, and are probably responsible for the marked and rapid diminution in the size of the spleen, and in the lymphadenoid type of the disease of the lymph glands. To this rapid disintegration of cellular elements in turn the constitutional symptoms are unquestionably due, which in some instances are so very marked, and may indeed assume very grave proportions.

In what manner the X-rays produce the ultimate beneficial effect upon the leucemic patient, whether through direct influence upon the primary etiological factor, or secondarily in consequence of the tissue destruction and the coincident liberation of specific antibodies, these are questions which at present can only be subjects of speculation.

As regards the final outcome, sufficient time has not elapsed since the report of the various cases to warrant any far-reaching conclusions. To speak of a cure, as Senn especially has done, is certainly not justifiable. His myeloid case, in fact, has already relapsed, and two other cases (Grosh-Stone, Ahrens) have died. The results, however, are nevertheless sufficiently encouraging to warrant the adoption of the X-ray treatment as a matter of routine in the management of these cases, in addition to the older methods, and especially the use of arsenic in the high doses suggested by Osler.

In conclusion, we should suggest that future reports be made somewhat more extensive than has been the case with the majority of those recorded so far, and that careful attention be directed to the blood changes not only for diagnostic purposes, but also in order to afford a control of the treatment instituted. Especially important in this sense is the behavior of the mast cells, which unfortunately has been neglected in most of the reports. It is interesting to note that in the case reported by Simon and Campbell, above referred to (not treated by X-rays), the mast cells remained high, even after all other symptoms of the disease had disappeared.

"FROM YOUTH TO HOARY AGE."

WHETHER moral suasion is superior to corporal punishment and should supersede it has been a mooted question ever since the days of Solomon's didactic and ex-cathedra statement, that to spare the rod was to spoil the child. The trend of modern medical civilization, however, has been undoubtedly to eliminate the latter. Scholars in the large public schools of Great Britain are no longer "hoisted or swished." The big white Czar of all the Russias, luckily for himself and his kingdom, abolished the knout before they became "busy" with the little bee, in the Japanese bonnet, that is now rendering so uneasy the head that wears the Slavic crown. Flogging has been done away with in the navy, and it is now a court-martial offense for an officer to strike an enlisted man. Even the assailant of the classical "Billy Patterson" is a fugitive from the outraged laws of an offended country, and there is no longer any opportunity for the professional exponent of humility to turn the other cheek.

"Moral suasion" is unquestionably a great force, and if it failed the other day, when some dozen guards of a homeopathic insane asylum sat by the river on the gunwale of an unmoored boat, with their brass buttons shining on their blue coats like the stars on a summer sea, and piteously begged an escaped lunatic, who was struggling in the rapid tide, to come back (like Lord Ullin's daughter), it was not their fault that the system did not work. This was undoubtedly the exception that proved the rule; the experiment that, while it failed, left the principle the same.

On the other hand, the question naturally arises, are we not at times, like the world, "governed too much," and does not a law, that may be unquestionably righteous and just for the masses, work often great injustice to the individual? Thus, that much-derided owner of the two dogs who cut two holes in his fence, a big one for the large dog and a little hole for the small one, may have cut much better than either he or his critics knew. For there might easily be circumstances in the canine existence that would render it very hard and humiliating for the little dog to pass through the big hole, even though it was much too large for him. Only a few weeks ago a judge on the bench in Virginia publicly announced that he unreservedly favored the restoration of the whip-

ping-post as a cure for the chronic wife-beating diathesis, and there are few members of the medical profession who will not agree with him. And yet this same judge, by the inflexibility of the statutes, would be compelled to mete out a heavier punishment to a starving woman who stole a loaf of bread for her hungry children than he would to "the man who would raise his hand against a woman save in love and kindness," whom the late Edwin Forrest anathematized so forcibly.

Luckily, however, a wise judge can, if he so desires, at least temper the wind and add the warmth of the judicial ermine to the scanty pelt of the shorn lamb when it is of tender years. That he does not always do it, however, is true, and the arrest, trial and subsequent conviction of a few boys for playing ball on a vacant lot, in a neighboring town, seems to be another instance of misapplied judicial zeal and a case where the fine points of the law would have been more honored in the breach of the offenders than in the observance of the municipal regulations.

As we have said, class legislation is always a delicate matter to undertake, and the age limit has more to do with the division of a population or a community of persons into sections than either the possession of wealth or the inheritance of social standing. Boys will be boys, and the production of a bat and a ball is two-thirds of a problem, of which the finding of an unoccupied field is a complete solution. For good, as the common-school education in this country undoubtedly is, there are few specimens of the primary classes that are able or willing to read the writing on the wall, particularly when it takes the form of a notice to trespassers, or an injunction to keep off the grass.

Of course, in a large city, where the lots are small, and where the passers-by are consequently in danger of being struck by the ball, or the neighbors are near enough to be disturbed by the noise inseparable from a congregation of boys, it would be impossible to permit the frequent gathering together of a youthful community, either in the name of baseball, football, marbles, or whatever game the season has brought in vogue. But even then verbal warning may be given, and we cannot help thinking that the popular indignation that seems to have arisen locally in this case might have been avoided if the village Dogberry had exercised a little tact, or if the magistrate, like "Father William," had only remembered the days of his youth. For there is a popular belief in the minds of all of us that we can only be young once, and though this seems to have been an overliberal estimate, in the case of these municipal authorities, yet a timely recollection of it is the key-note of all successful government.

It may be true that the laws are not enacted for the individual, but are framed for the masses, and of necessity must be the same. Yet, even then the sauce for the gosling need not be that for the gander, and the judge on the bench always has the ability to make the punishment fit the crime to a degree at least sufficient to remember that old heads do not grow on young shoulders, and that, as a rule, children do not wear hats of men's sizes.

There is a trite old proverb that "reformed rakes make the best of husbands." If this be true we cannot say, but we should not care to bring our case before a judge in whom age had staled and custom withered all the attributes of youth, and whose recollections of the past were tinged and saddened by his present aches and pains.

Both Solomon and David lived extremely happy lives,
And enjoyed themselves immensely with their horses and their wives,
But, when their blood ran colder, they were seized with aches and qualms,
Then Solomon wrote his Proverbs, and David wrote his Psalms.

ECHOES AND NEWS.

NEW YORK.

Convention of Chemists.—The first annual convention of the Society of Chemical Industry to be held in America will begin in this city at the Chemists' Club on Wednesday, September 7, and will continue until September 12. The foreign delegation will then be taken aboard a special train as the guests of the New York members for a trip through the South and Middle West. The society is an international organization, and members will be present from many foreign countries. One feature of the meeting will be a visit of inspection to the larger manufacturing plants all through this country. It is expected that many important questions relating to the chemical industry will be considered.

St. John's Guild.—Since July the seaside hospital of St. John's Guild has treated over 2,200 patients, and its floating hospital has carried out over 25,000 children and their mothers. This summer, as the Health Department has testified, has been marked by an unusually large amount of suffering among the children of the poor, and to deal with the emergency properly the guild has been put to so much expense that it now needs $15,000 additional to enable it to continue its hospitals in operation during the summer. The mere announcement of that need ought to be enough to bring in the money at once for so noble and necessary an institution of humanity. The hospitals are in charge of physicians of special ability, Dr. Abraham Jacobi being the president of its medical board, and in every respect the guild deserves support and commendation.

Bronx Typhoid.—There are now over 200 cases of typhoid fever in the Bronx, according to a canvass made

among private physicians there by Dr. M. S. Gregory, Acting Superintendent of Bellevue Hospital, and other officials of that hospital and its allied institutions. This number is far above the normal rate, and the presence of so many cases is renewing the fears felt a month ago, when many cases of typhoid were reported among the Italians who live in the Bedford Park section of the Bronx and work on the Jerome Park Reservoir. The number of patients is so large that it is causing Bellevue and its allied hospitals trouble in caring for them. Fordham Hospital, which is nearest to the place where their cases are said to have originated, has only twenty cots in its medical ward, and the overflow has been relieved by sending such patients to Harlem Hospital and to the Bellevue and allied hospitals, neither of which has much extra room. Dr. Gregory has given orders for the erection of a temporary cottage on the grounds of the Fordham Hospital. This will provide room for about a dozen typhoid patients. The epidemic is apparently of a mild type, only two persons have died of the malady during the first three weeks of August.

Sydenham Hospital Charges.—Charges have been made to the State Board of Charities against the trustees and managers of the Sydenham Post Graduate Hospital, at No. 339 East One Hundred and Sixteenth Street, by four physicians formerly attached to its staff. The complainants are Dr. Salo Cohn, Dr. Louis Lichtschein, Dr. A. L. Goldwater, and Dr. B. M. Feldman. Two of the four allege that they were required to pay for appointment of the hospital staff a certain sum down and an additional amount monthly. It is also charged in sixteen specifications that the hospital has been conducted "in an unsanitary, unlawful, negligent and improper manner." Tuberculosis patients are said to have been kept in wards with other patients, unlawful autopsies are alleged to have been held, violation of corporation ordinances in the matter of fire escapes is asserted, substitution of medicines is said to have been practised, and other abuses are alleged. The hospital was incorporated in June, 1892, and licensed in February, 1903, under a law passed in 1899. It receives no State aid, but because of the license granted by the State Charities Board, is subject to its inspection and regulation. Its president is W. L. Spiegelberg, whose connection with the hospital dates back only to January last, a period subsequent to the retirement of the physicians who now prefer charges. The hospital, as a result of the charges, which all its officers deny absolutely, was thrown open for public inspection yesterday. To the layman it appeared well equipped and properly conducted. The directors will meet to-night to consider the charges and decide on a course of action.

School Hygiene and the Growing Child.—In an article for the Educational Supplement of the New York Times, Dr. L. E. La Fetra discusses the relationship of physical, intellectual and moral growth and development. At whatever point in the educational system the boy has to stop to take up his life work, up to that point his training should have been broad and symmetrical; the training of the body should be recognized to be as important as that of the mind. The schoolroom should be large in proportion to the number of scholars, well lighted and so arranged that the light may come in on the left hand side of the pupils. Good ventilation is important, the current of air should pass from inlets high up on the wall to outlets low down on the same wall; the temperature should be between 64° and 62° F. for the larger children, 68° F. for the smaller, the rooms heated by indirect radiation. Besides the recitation rooms, the school building should have a gymnasium with shower baths and a swimming tank if possible. It is important to have sufficient ground around the school building for athletic sports; in the city the roofs could be used for playgrounds. To obtain the best physical development, which statistics show is essential to the highest intellectual growth, it is necessary in our civilized communities, where the natural activities of the average child have little place, to make gymnastic exercises a part of the general curriculum. Exercise, especially highly co-ordinated movements, develop not only the muscles, but the brain as well, and team games tend to raise the moral character. Bathing is of equal importance, for it stimulates the nervous system and prevents children catching cold, besides acting as a cleansing agent. Overfatigue must be guarded against, especially in children who are of a nervous disposition, anemic or growing rapidly; girls entering on the adolescent period are extremely liable to overfatigue. Signs of overfatigue: Awaking unrefreshed in the morning, inability to concentrate the attention, loss of memory and irritability should be watched for and guarded against. Competitive examinations are important factors in causing overfatigue, and should be eliminated as far as possible by substituting the daily recitation marks. The daily medical inspection of schools is a commendable feature of recent school regime. On the intellectual side, too much stress is put upon certain fads, and not enough on the fundamental studies. The recitation periods should be short, with the most difficult subjects in the morning. Elective studies have no place in any grade below the latter part of the high school; disciplinary studies are of the greatest importance. In the higher grades hygiene and some knowledge of the processes of reproduction should be taught. Manual training is of great value in that it combines physical and mental training. Courses in domestic science are valuable adjuncts to education of girls.

Resignation of Dr. Millican.—Having had repeated for the third time an invitation to go to St. Louis and take over the management and editorship of the St. Louis *Medical Review*, Dr. Kenneth W. Millican, of New York city, has decided to accept. For six years Dr. Millican has been a member of the editorial staff of the New York *Medical Journal*, and in this capacity has impressed its readers with his broad culture, untiring energy and unusual literary ability. In losing Dr. Millican from the position of Associate Editor, the New York *Medical Journal* suffers a loss that will not be easily repaired. In his new relations the MEDICAL NEWS bespeaks for Dr. Millican an early recognition of his worth, and wishes him and the St. Louis *Medical Review* the success which their combination merits.

PHILADELPHIA.

Additions to Almshouse.—Estimates have been asked for the construction of seven new buildings for the Almshouse being erected in the Forty-first Ward. The administration building has already been completed.

Pittsburg to Build Filtration Plant.—Mayor Hays has signed the ordinance authorizing the issue of $5,000,000 bonds for the construction of a filtration plant. This measure has been agitated for a long time, and even now the city controller will contest the ordinance on the ground of a technical flaw in its passage.

New County Medical Societies.—The physicians of two Pennsylvania counties have recently organized medical societies. On July 29 a society of 15 members was formed at Bedford, in Bedford County. Dr. S. G. Statler, of Alum Bank, was elected the first president. August 25, the physicians of Adams County formed a society at Gettysburg, with Dr. J. W. C. O'Neal, of that place, as president.

Pennsylvania Medical Journal.—The editorial management of this journal favors an increase in size of 8

or 16 pages. This change would permit the publication of papers read before the county societies; at present there is barely room for those read at the meeting of the State organization. The Bucks County society has endorsed this proposed increase, and the question will probably be presented to the State society at the coming meeting.

Medical Society of the State of Pennsylvania.—The annual meeting of this society will be held in Carnegie Hall, Pittsburg, September 27 to 29, 1904, under the presidency of Dr. W. B. Ulrich, of Chester. As at the meeting of last year, two sections will be held on the second day and the first session of the third day. The addresses will be given by the following: Medicine, Dr. Henry Beates, Jr., Philadelphia; Surgery, Dr. W. D. Hamaker, Meadville; Obstetrics, Dr. X. O. Werder, Pittsburg; Hygiene and State Medicine, Dr. A. C. Abbott, Philadelphia; Neurology, Dr. W. K. Walker, Dixmont; Laryngology, Dr. D. W. Mears, Scranton.

Disinfection with Ozone.—An experiment is soon to be tried in Philadelphia which may be of value to communities that are in need of purer water supplies than they now enjoy. The New York *Tribune* states that a private corporation in that city is erecting a plant on the banks of the Schuylkill for the purpose of showing the superiority of disinfection with ozone over the system of sand filtration adopted by the municipality and already in service along the Delaware. The method about to be tried has been introduced on a small scale in two or three foreign cities, but is practically unknown in America. It differs from that employed by Albert E. Wolf, of this city, ten or twelve years ago, and by M. Hermite, in France. Those men treated salt water with electricity, and thus liberated both ozone and chlorine. The new process produces only the former and obtains it from the air. By means of suitable electrical apparatus the oxygen is separated from the other gases with which it is associated, and is so modified as to acquire powerful germicidal properties. These are exercised upon contaminated water if the ozone is permitted to bubble up through the fluid, and at the same time the latter is clarified and deodorized. Up to the present time filtration has done more for the purification of water in which the bacteria of typhoid fever and other diseases are present than any other mode of treatment. Its benefits are not uniform. Through mistakes of administration it occasionally fails to yield the expected results. At best it only reduces the number of microbes. It does not completely eliminate them. Still, it has materially lowered the death rate in many localities which formerly suffered a heavy mortality. To convince disinterested sanitary engineers that the use of ozone will prove more satisfactory in the long run will be by no means easy. A system which works admirably in the laboratory does not always behave equally well on a large scale. It is easy to believe that if a globule of ozone comes in contact with a mischievous bacillus the latter will be instantly killed. Whether a sufficiently thorough commingling of the gas with the water can be insured to reach all the germs in the fluid is another question. A second essential to efficiency is continuity of operation. If the machinery gets out of order there must be an interruption either of the water supply or of the disinfection, and instances of the latter kind appear to have occurred at Wiesbaden. It is to be hoped that the apparatus which is about to be installed in Philadelphia will have an endurance test, to clear up uncertainty on this point. If the men under whose auspices the venture is made can also demonstrate the economy of the process, they will overcome doubts which have been entertained by experts who apparently have none regarding its excellence. Cities which cannot supervise and control the territory from which their water supply comes are exposed to peculiar danger. Practically all of the typhoid epidemics which occur in this country and Europe result from such inability to prevent contamination. The only resource left in cases of that kind is to purify the water before it is distributed for consumption. The number of communities which have neglected to adopt one safeguard or another is astonishingly large. In the near future the scope of their choice may be considerably widened. In a dozen or more places the copper sulphate system is undergoing a trial this year, and before many more months have elapsed a correct judgment of its value should be possible. If the regeneration of water from the filthy and poisonous Schuylkill should prove effective and cheap, an additional instrument for much needed sanitation will be available.

CHICAGO.

Election of Dr. James.—President Edmund J. James, of Northwestern University, has been offered and has accepted the presidency of the University of Illinois, and will assume the duties of his new office November 1.

Laboratory for the State Board of Health Established.—It is said that the State Board of Health has secured orders in Springfield for a laboratory which is being equipped with the chemical and biological apparatus necessary for carrying on the work of the Board, with special reference to examinations of water, the prevention of communicable diseases, tuberculosis, etc.

The Milk Question.—The *Weekly Bulletin* of the Chicago Health Department has the following to say with reference to the question of milk: "The dealers in the city, who receive milk, were given individual warning to the effect that such milk was from cows that were being improperly fed, and that they must not receive it or sell it in the city of Chicago. Those who did not comply have been prosecuted and fined. A great many dealers have also been fined for not returning their milk cans to the shipper clean and dry. It is a well-known fact that a small amount of sour milk will readily sour a large can of fresh milk. This sour milk produces digestive troubles in children, such as vomiting, flatulence, and diarrhea. Other diseases, such as tuberculosis, which is very prevalent among cows, may be conveyed by milk. The dairy inspectors are paying especial attention to this fact."

Conveyance of Typhoid Fever, Scarlet Fever and Diphtheria by Milk.—"Typhoid fever, scarlet fever and diphtheria are sometimes conveyed by milk; especially typhoid, if the cans and bottles are washed in foul water and not sterilized. Cities well supplied with water of good quality and having a modern sewerage system derive typhoid fever only from contaminated country milk or vegetables or the return of people in the autumn from less sanitary places. The bacteria in milk produce acids and toxins, which are injurious to infants and invalids. To destroy these milk is often pasteurized. This, however, is somewhat objectionable, as it destroys certain enzymes that are necessary for the digestion of the milk. It is easy enough by diluting pasteurized cow's milk and adding milk sugar to obtain milk identical in per cent. of its principal constituents with mother's milk, but the trouble due to the indigestibility of the caseins remains, therefore, mother's milk is about the only thing for the baby."

Improvement in the Public Water Supply.—"For the second time in ten years a rainfall of more than three-quarters of an inch in twenty-four hours has failed to cause contamination of the public water supply of Chicago. The first on record was that following the rainfall of July 31, which was more than

nine-tenths of an inch. During the twenty-four hours ending at 7 P. M., Aug. 19, there was a precipitation of more than one and one-fourth (1.27) inches, but the chemical determinations of Aug. 20 showed a purer water at each of the nine pumping stations than samples taken seven miles from shore and identical with samples taken twelve miles from shore. There is no obvious or plausible reason for this but the continuous operation of the drainage channel. This is the fifth year that an average of more than 300,000 cubic feet per minute, night and day, has been flowing from the lake down the Desplaines and Illinois valleys, and during this time there has been the reduction in deaths from the impure water diseases shown in the following table—the dividing line being January, 1900, date of opening the channel:

Deaths from—	Four Years. 1896-1899	Four Years. 1900-1903.
Acute intestinal diseases.....	8,119	8,898
Rate per 1,000 of population.....	16.41	12.44
Typhoid fever.....	2,366	2,235
Rate per 1,000 of population.....	3.68	3.10

"If the rate of the four years 1896-1899, before the opening of the drainage channel, had obtained during the last four years, there would have been 11,724 deaths from the acute intestinal diseases and 2,629 from typhoid fever, or 2,826 more from the former and 394 more from the latter (a total of 3,220) than did actually occur. The money value of these 3,220 lives—16,100,000—is only one item to be placed to the life-saving credit of the drainage channel; a larger, but intangible amount would accrue, if physical suffering of the victims, mental suffering of parents, wives and husbands and impairment of vital resistance of the survivors could be figured out in dollars and cents. From the standpoint of public health the drainage channel is the best investment Chicago ever made."

Decreased Death Rate for August.—The average August death rate of the last decade was 1.84 per one thousand of population, and the lowest during that period was 14.53 in 1901. For the first twenty days of August the rate was 12.67, and for the week ending August 20, the 437 deaths reported represent an annual rate of only 11.62. These figures show a reduction of 20 per cent. from the previous lowest, and of 31 per cent. from the previous August average. The deaths numbered 437, of which 108 were from intestinal diseases; 59 from consumption; 34 from violence; 29 from Bright's disease; 26 from cancer, and 25 from pneumonia.

A "Hospital" of the Past.—"Twenty-five years ago the Cook County Hospital," said Dr. I. N. Danforth, "stood at the corner of Eighteenth and Arnold streets. In close proximity was a slaughter house where a chime of ear-splitting squeals testified to the constant march of porcine mortality, while frequent odors of "rendering" tanks added most convincing confirmatory evidence. The neighborhood was then infested with lager beer saloons, soap factories, cooper shops, and other noisy and fragrant adjuncts, while the constant snorting of locomotives and the rumble of railway cars, including the ceaseless switching of freight cars made up a pandemonium sufficient to weary a well man and drive a sick man crazy. Smoke, dust, dirt of every conceivable kind, darkened the air, offended the nostrils, provoked "sternuation" (vide Sir Walter Scott), and soiled face and hands and clothing, although most of the hands and faces found in that locality were not essentially changed thereby. In such a locality as this and amid such surroundings as these, stood the old County Hospital—but let us look at the institution itself. The edifice was an ugly rambling affair, built I know not when or for what purpose; when I first knew it in 1867, it was thoroughly out of repair, and was odiously repulsive in all its appointments. It was ill-kept; the wards were dirty, the ceilings grimy, the furniture unclean, the beds and bedding were unfit for the steerage of an emigrant vessel, and the whole aspect and make-up of the concern was a disgrace to Chicago and Cook county. Rats and mice galloped about the corridors, infested the wards, and frequently invaded the beds of the patients. Cockroaches abounded in solid battalions; mosquitoes and flies in hungry clouds buzzed through the wards; while an "offensive bug which infests beds," called by a gentleman named Baird the *Cimex lectularius*, provoked a deal of both profanity and scratching on the part of patients who were sufficiently vigorous to do either or both. A more detailed description of this hideous concern would only set forth its repulsiveness in stronger colors. It was *all* bad, except the Medical Board, which was generally made up of able devoted men who did the best they could to make the institution respectable. The nursing service was unique; the nurses were always political appointees; that is, men and women who in some way could "influence" voters. The "rich Irish brogue" which so captivated that old political peacock, Gen. Scott, during his barren Presidential campaign, was "endemic" among the nurses, although a German or Scandinavian expletive, occasionally broke the silence and varied the discordant jargon. Of course, the cooking was execrable and the patients constantly complained of their miserable food, and of the disgusting manner in which it was served. In the year 1878, the Chicago daily papers, being incited thereto by a deputation of physicians—whereof the writer was one—investigated the Cook County Hospital, and proceeded to mercilessly expose its disgraceful condition—in the name of the outraged sick poor they demanded a thorough reform, and they got it. Never did a Board of County Commissioners get a more thorough scorching; never did said body more thoroughly deserve such scorching, and never did a drastic remedy produce more immediate and radical results. The present stately hospital of Cook county is directly due to the potent influence of the daily papers—the newspaper press—and its influence was experienced none too soon."

GENERAL.

Officers of Pan-American Medical Congress.—The following officers of the Fourth Pan-American Medical Congress have been appointed: Dr. Julio Ycaza, president; Dr. Manuel Coroalles, vice-president; Dr. José E. Calvo, secretary; Dr. Pedro de Obarrio, treasurer, and Drs. J. W. Ross, J. Tomaselli, M. Gasteazoro, committee.

New York and New England Association of Railway Surgeons.—The fourteenth annual meeting of the New York and New England Association of Railway Surgeons will be held at the Academy of Medicine, New York City, Nov. 17 and 18, 1904, under the presidency of Dr. C. G. J. Finn, of Hempstead, Long Island. Railway officials and all surgeons interested in this work are cordially invited to attend.

The Aquiline Nose and Voice Development.—Dr. Louis Robinson asserts that the aquiline nose is requisite to a full development of the human voice. His contention as to the origin of this feature, according to the *Medical Times*, is that through the night of unrecorded time during which primitive man was slowly and painfully progressing toward civilization, the voice was the only rational means of exercising influence. Oratorical ability and a sonorous voice thus became of exceeding importance to the aspiring and ambitious, and the ulti-

mate formation of an aquiline-nosed race would become the necessary result of the better assured survival of such favorably endowed individuals. Thus, says the *Popular Science News,* the long nose would tend to become masterful, to form; first, an aristocracy, and ultimately so to leaven a people as to insure their dominance, as was the case with the Romans. Dr. Robinson cites the North American Indian, the Moaris and the Basuto negroes, among whom are the celebrated Zulus, as instances of large-nosed and oratorical peoples.

The Waldeck-Rousseau Operation.—M. Waldeck-Rousseau was operated on on May 5 for cancer of the liver. According to the general understanding the operation was only partly successful, but it enabled the patient to gain strength enough to warrant his removal from Paris to Corbeil, where it was hoped the country air would restore his strength entirely. A second operation was performed on August 10 by Professor Kehr and Dr. Armour, a Canadian surgeon, assisted by three French surgeons, after a consultation at which it was decided that since the liver had ceased to perform its functions an immediate operation was the only hope of saving the patient's life. It at first appeared that the operation would prove successful. But the pulse became more feeble, and despite the administration of injections M. Waldeck-Rousseau gradually sank and died without gaining consciousness. Professor Hans Kehr, of Halberstadt, in the *Medicinische Wochenschrift,* defends himself against the attacks of French medical journals on the operation performed on ex-Premier Waldeck-Rousseau. He says that the patient had absolutely no chance to recover without an operation, whereas an operation saves 34 per cent. of such cases. M. Waldeck-Rousseau had nothing to lose through the operation, since he had only a few weeks, perhaps months, to live, and an operation was the only hope of saving him.

Report of Committee on Determination in England.—The English Inter-Departmental Committee on Physical Deterioration has issued its report in London, and makes the following recommendations: For the collection of definite data bearing upon the physical condition of the population a permanent anthropometric survey should be organized to take measurements of children and young persons in schools and factories. A register of sickness not confined to infectious diseases should be established, and an advisory council created, the composition of which might be modeled on the French Consultative Committee of Public Health, to apply information derived from the anthropometric survey and the register of sickness, and to advise the Government on points concerning public health; and the local authority, as an experimental effort in the direction of fixing a standard of overcrowding, should notify in certain of the worst districts that after a given date, no crowding in excess of such standard would be permitted. On the subject of alcoholism, the committee advocates systematic practical training of teachers to enable them to give rational instruction in schools on laws of health, including demonstrations of the physical evils caused by drinking, whereby more may be done to check degeneration resulting from drink, by bringing home to men and women the fatal effects of alcohol on physical efficiency. Impressed with the enormous sacrifice of infant life due to insufficient or improper feeding, the committee believes the ultimate remedy lies in the instruction of girls in the process of infant feeding and management, and recommend the establishment of health associations for training of mothers in hygiene, and that girls over fourteen might be made to attend occasionally municipal crèches wherever established. A further recommendation is to prohibit the sale of tobacco and cigarettes to children.

Copper as a Typhoid Germicide.—Attention has lately been attracted to the confident announcement made by Dr. Edward Martin, of Philadelphia, Director of Public Health and Charities, that water infected with typhoid germs may be sterilized without boiling or filtering, by permitting it to stand in copper vessels for four hours in the ordinary temperature of living rooms, or for twenty-four hours in a refrigerator. Dr. Martin further states that the specific infection of Asiatic cholera in water may be destroyed by the same means. This hypothesis had previously attracted some attention in Washington, and a suggestion has been made that the soldiers of the United States Army be provided with canteens made of copper, to the end that the always large and hitherto unavoidable risk of typhoid fever, dysentery, and like diseases in camps and barracks may be minimized. In editorial comment, the New York *Times* says, that very likely water allowed to stand in copper vessels until it has taken up a certain amount of the metal in the form of soluble salts is sterilized, such salts acting as germicides with a special antipathy for typhoid and cholera bacilli. This might be true, and yet the discovery not be the priceless boon to suffering humanity which at first glance it would seem to be. There are a number of possible additions to water which would have this effect, but which the conscientious chemist would hesitate to recommend for general family use. As the rule water, if pure and wholly free from carbonic acid, will not attack copper, but when a surface of that metal is exposed to the action of air and water in combination it is more or less energetically attacked, especially if any acid is present. Inasmuch as unboiled water usually and moist air always contains carbonic acid, copper exposed to the action of either is more or less rapidly coated with a film of basic carbonate, popularly but incorrectly called verdigris. Copper is a metal which is readily dissolved in the weakest acids, and also in weak alkaline and saline solutions. Up to this time it has been considered a safe generalization, verified by numberless observations and experiments, that all potable waters will dissolve more or less copper and that all its soluble salts are more or less energetically poisonous. Some of the salts of copper, notably its basic carbonate, are not soluble in cold water, and may be removed by filtration, but most of them are both soluble and poisonous, and some of these are likely to be formed with the carbonate, or in acid water without it. The action of the soluble salts of copper on the human system is indicated by nausea, violent headaches, cramps, and acute pains in the stomach and bowels, faintness, convulsions, and even death. Boiling suspected water is a good deal more troublesome, no doubt, than storing it in copper vessels, but it is preferable from every point of view, and effective filtration is better than either.

Fair for Nassau Hospital.—A fair for the benefit of the Nassau Hospital, of Mineola, will be held at Mr. and Mrs. Clarence Mackay's home, Harbor Hill, Roslyn, L. I., on Saturday afternoon, September 24, from 1 to 7.

Roentgen Ray Society.—The fifth annual meeting of the American Roentgen Ray Society will be held at the Louisiana Building, 911 North Vandeventer avenue, St. Louis, Mo., Sept. 9, 10, 12 and 13.

OBITUARY.

Dr. William Rhys Pryor, of New York city, died August 26, in his forty-seventh year, in St. Vincent's Hospital, where he had been ill for a fortnight. He was one of the most distinguished practitioners of obstetrics and gynecology in the country. Dr. Pryor performed an operation a few days ago at Blooming Grove, Pa., in a room in which the temperature was 104° F. After the

operation he collapsed. He was brought back to the city and taken to St. Vincent's Hospital. He was a son of ex-Justice Roger A. Pryor, of the Supreme Court. Although he had a large practice, his work was mostly charity work among the poor. He was graduated from the College of Physicians and Surgeons in 1881. Dr. Pryor had written several books of value to his professional brethren, among them "Text-Book of Gynecology." In addition to many medical and scientific societies, he was a member of the Manhattan, Colonial and New York clubs.

Dr. Charles Newton, of New York city, died at Nantucket, Mass., on Sunday, August 7. Dr. Newton graduated at Bellevue in 1884, became a well-known practising New York physician, and was for many years Surgeon of the Ninth Infantry, N. G. S. N. Y. He was a member of many medical societies and fraternities.

SOCIETY PROCEEDINGS.

CHICAGO ACADEMY OF MEDICINE.

Regular Meeting, held March 11, 1904.

The President, Wm. Allen Pusey, M.D., in the Chair.

Silver Salts in Gonorrhea.—Dr. Wm. L. Baum read a paper on this subject.

Dr. Fenton B. Turck stated that some time ago Dr. Howard A. Kelly, of Baltimore, followed out some of the work done by Guyon, of distending the bladder and observing the changes in the mucous membrane. Kelly used air instead of water. He found that upon distention it produced the usual anemia, followed subsequently by hyperemia, and that this process being continued, the condition found in cystitis was very much improved. Kelly presented some plates showing the differences before and after treatment. The question arose as to what was the physiological action of such pressure. It was evidently not due to the water or fluid used, but to the tension produced upon the vesical walls. Intermittent pressure or tension is a universal stimulant of all protoplasm. Various mechanical methods of stimulating the muscles, as used in the laboratory were mentioned illustrating tension in its various forms as a universal stimulant. According to the recent observations of Mathews and Wicher all protoplasmic activity was excited by various forms of motion. Parthogenesis of the egg of the starfish was produced by intermittent mechanical agitation. Tension being thus recognized, by most observers, as a universal stimulant it is not surprising to notice that similar results are obtained in the urethra. The question now obtains, What was the curative effect or what was the exact cause that brought about restoration?

Dr. Turck spoke, first, of hyperemia, saying it was recognized and admitted that hyperemia was the result of such tension, but only after the tension had been released. If the tension was continuous, there would be no such favorable result. It must be intermittent in order to act as a stimulus, and this tension and the release of tension must be more or less abrupt, the result being a greater activity on the part of the capillaries and of the contractile tissue. Rhythmical motion resulted from such tension, and this motion continued after its removal. It did not mean simply that passive congestion or stasis of the blood vessels was brought about, but that more blood passed a certain point within a given time than before. Such physiological hyperemia resulted in more active metabolism of the cellular tissues. With regard to increased leucocytosis being one of the important changes that takes place, he said that various stimulants or various exercises caused increased leucocytosis by bringing the leucocytes more to the periphery. There was now among the German and French investigators considerable controversy as to the value of leucocytosis in the curative processes of infection. It was known that hyperemia produced certain other conditions which better explains the various changes that occur. When more blood passed a given point at one time than at another, *i.e.*, a larger amount of blood brought to that part, a larger amount of activity occurs as the result of more rapid stimulation; there is a greater bactericidal effect, as well as antitoxic properties in the serum. This effect may be local or general. Recent experiments show a local effect upon the eyes of rabbits after artificial hyperemia, this hyperemia producing an artificial immunity. The studies the speaker had made had been in the direction of producing such stimulation in animals by mechanical means, showing the great immunity which can be produced by either mechanical or physical means, such as, for example, heat. Heat stimulation caused rapid hyperemia, this hyperemia acting with bactericidal and antitoxic effect. Attention was called to the effects of heat stimulation produced upon the arm in a case of local infection in which the continuous heat stimulation produced increased hyperemia, the latter causing an effect upon the bacteria already present, and the antitoxic effect in the serum curing the local infection. If further experiments could be carried on, they would very probably show that the hyperemia thus produced, that is to say, the more rapid circulatory effect in the urethra was the real factor in producing the bactericidal and antitoxic effect. The embryonal cells multiply and displace the old necrosed epithelium. He said it would be an interesting experiment to try the effect of tension produced by air instead of water, getting alternate pressure, and producing intense hyperemia in this structure, and experiments would probably show that air was equally as valuable as water for this purpose. He had found in other mucous membranes, such as those of the colon and stomach, quite as remarkable results were obtained by this alternate tension with air as with water. In fact, he thought air was preferable to the use of water. In water we have an incompressible substance, while in air we have a more elastic body, and considerable tension could be brought about without any harm, such tension resulting in a cushion-like effect, producing more powerful stimulation and resultant contractions. He further called attention to the experiments that had been made along this line of cushion-like effects by means of air. These experiments showed that such tension and its withdrawal was the most powerful of all local and general stimulants at the command of the physician. Heat sometimes might be increased, but the principal effect was derived from tension, and its abrupt withdrawal.

Dr. Turck stated that when he was a student in Berlin he saw a very interesting case in the nose and throat clinic of Professor Fraenkel, of pachyderma of the vocal cord, the diagnosis having been confirmed by the Professor himself. The patient was a woman who had frequent injections of iodine and of weak nitrate of silver solutions into the larynx some time before, and the question was raised whether this had not a good deal to do with the origin of the pachyderma of the cord. The woman was markedly anemic, which point was also brought out as a contributing effect, the anemia causing this pachyderma. But the work done by Dr. Fütterer showed that there was a trauma produced first, and in the center of this growth metaplasia occurred. One was almost compelled to accept the findings of Dr. Fütterer as a true metaplasia. In the case he reported

of pachyderma of the vocal cord chemical trauma undoubtedly played the important rôle. It was supposed to have been the starting-point of the pachyderma in the presence of anemia. One realizes how variable clinical conditions might be, but on the work of Dr. Fütterer one had the absolute experimental proof in the removal of a section, showing the ingrowing of normal glandular tissue and springing almost spontaneously from the center of this was the development of metaplasia.

Professor C. S. N. Hallberg asked whether or not it was the opinion of the essayist that the organic compounds were preferable to the nitrates? What led to the production of the organic compounds was that they were not caustic; that they would not form insoluble compounds with albumin or insoluble chlorides, and that it was these particular properties which gave them preference over the nitrates. He understood the essayist to say that the first effect of the silver compounds on the epithelia was favorable to exfoliation. He asked whether this was not produced in an equal degree by the nitrates as well as by the organic compounds?

Dr. Baum, replying to Dr. Turck, said that air was difficult to use in the urethra with an ordinary syringe. While it was of light specific gravity, it had one very great drawback in the treatment of diseases of the urethra, or in closed tubes of this kind, and that was that air was not a pleasant thing in cases in which there were erosions of the mucous membrane, so that air distention would have to give way to the more common form of distention with water, which was not only practicable, but could be obtained at any time. It could be kept in the urethra, whereas air would escape in spite of everything by the side and reduce tension too rapidly.

In regard to the strength of the various silver solutions, he did not see that the quantity of silver had any appreciable effect upon the results obtained, except there were some silver salts used in which the subjective symptoms were so much pleasanter than they were when other silver salts were used in preference to some of the later ones. As to nitrate of silver, there was no question in the author's mind, but what the subjective symptoms played an important rôle as far as the confidence of the patient and the ultimate results to be attained were concerned. There was much to be said about nitrate of silver in those cases where the resistance of the mucous membrane is greater, and especially in cases of posterior urithritis, the results were much more favorable than they were from the use of the organic silver salts. This was particularly true of gonorrheal cystitis. As to the comparison between the results obtained by the instillation of nitrate of silver and the use of the organic silver compound, he thought nitrate of silver was far preferable to the others. He looked upon it as being due to the one fact which must not be left out of consideration, namely, the mucous membrane of the bladder was non-absorptive, the exfoliation, which was induced by contact of the drug with the upper layers of the mucosa, was greater, and inasmuch as the penetration of the gonococci was not so great, for that reason, the nitrate of silver was preferable, and followed by much better results. In conditions of the urethra, where there was absorption probably, with a tendency toward infiltration into the submucosa, pressure and other methods were preferable. Referring to the remarks of Dr. Turck in regard to tension, as far as the bladder was concerned, he stated that practically the reverse applied to what it did in the urethra, and the use of nitrate of silver and of the organic silver salts was distinct when applied to the bladder or when used in the urethra.

Epithelial Metaplasia in the Stomach.—Dr. Gustav Fütterer read a paper on this subject, and gave a demonstration. Metaplasia properly so-called means metamorphosis of well differentiated cell structure into another equally well differentiated type. Pseudo- metaplasia designates changes of form due to mechanical conditions, but not of type. Change, for instance, of cylindrical epithelial cells into squamous epithelial cells, with all their characteristics (prickle cells, concentric arrangement and hornification) constitutes genuine metaplasia. Cylindric epithelial cells in a cyst flattened by pressure of the cyst contents retain the character of cylindric epithelial cells, and are instances, therefore, of pseudo-metaplasia. The terms anaplasia of Hansemann and cataplasia of Benecke designate a loss of differentiation, with increased power of proliferation. Physiologic metaplasia occurs in the stomach of the edentata (bradypus, halmaturus and manis), and in the stomach of the oviparous echidna; all masticate with their stomach, which plays the part of the crop in birds. Physiologic metaplasia has been found in the cat's trachea, which in fetal and young cats is lined with cylindric epithelium, while in the adult squamous epithelium is found in a certain spot of the trachea. Genuine epithelial metaplasias have been observed in the nose, on the tonsils, in the larynx, trachea, in bronchial tubes, in the lung cavity, in the middle ear, gall-bladder, renal pelvis, ureters, bladder, urethra, uterus, vagina and rectum. The literature, particularly of gall-bladder and genito-urinary carcinoma, demonstrated the close relationship between metaplasia and development of carcinoma. The only case of metaplasia in the digestive tract, reported is that of Bohm. Bohm reported a cancroid originating from the rectal mucosa, with an epithelial lining like that of the epidermis. Dr. Fütterer made 92 experiments on rabbits; an inch square of the mucous membrane and mucosa muscularis of the pyloric end was removed. Two instances of metaplasia were found in December, 1903, and in March, 1904. Examination in the first case revealed that the artificial defect was covered with mucous membrane differing from the rest in hardness and thickness. In the middle, thereof a column of striated squamous epithelium branching deeply into the muscularis almost reaching the serosa was revealed by the microscope. The squamous epithelial nature of this column was indubitable. Hornification of the parts near the mucosa was shown by Gram's method. The origin of the squamous epithelium was plainly traceable to a very few (two to four) glands of mucosa. The growth pressure of this column was evident by its invagination of the muscularis, which was pushed through the stomach muscular wall almost to the serosa, without perforation. In this case the squamous epithelium indubitably originated from epithelial cells of mucosa glands, and not from an aberrant germinal deposit. The squamous epithelium was found in the center of the mucosa covering the artificial defect. No squamous cells were found in the surroundings.

Dr. Emil Ries said it was hard for him to conceive why there should be so much difference of opinion regarding metaplasia because embryologically there was no question about such a thing taking place right along normally. He could not see why cells which had such abilities during embryological development should not have such abilities later in life. Ordinarily, defects of epithelium were covered over with the same epithelium that had been there before, with restrictions and limitations. In covering over defects in the uterus, as, for instance, on the placental site after labor, the cells which grew over and covered the defect were ultimately typical columnar epithelial cells. But some research

which the author undertook years ago and which he said had been confirmed in an exhaustive paper by Wormser recently, had demonstrated various kinds of epithelial cells which markedly deviated from the columnar type. Ultimately, however, they returned to the columnar type; through successive phases of metaplasia these cells returned to the normal condition of the surrounding epithelium. The question of metaplasia in organs apart from the question of tumor formation had been particularly interesting to the gynecologist, because of the formation of erosions on the vaginal portion, which had been a much mooted question during many years.

He explained that on the cervix there occurred the formation of columnar epithelium in places where ordinarily stratified epithelium was present. This had been observed repeatedly to occur in islands, so that one could not say that the columnar epithelium from the inside of the uterus had grown out on the vaginal portion and had formed columnar epithelium there, but islands of columnar epithelium were found on the vaginal portion surrounded by stratified epithelium all around. There was no direct connection between the columnar epithelium on the inside of the uterus, and the columnar epithelium in the erosion. It had been said that in these cases we had to deal with remnants of the embryonic columnar epithelium which lined Müller's duct, the rest of the vaginal portion being covered with stratified epithelium, but a few islands had remained over. Under the leadership of Carl Ruge, it was asserted that columnar epithelium forms on stratified epithelium by the process of throwing off all layers except the basal layer, which continued to grow as columnar epithelium. But this would appear hard to prove because the only known function of the basal layer of stratified epithelium was to produce numerous layers different from columnar epithelium. If one scraped off any of the skin surface, and left the basal layer, there would be seen a new formation of stratified epithelium. In this erosion we had a type of metaplasia which had been observed very many times, and on which some experiments had been carried out, particularly with pyroligneous acid, which had been used in the treatment of erosions. If one poured into the speculum pyroligneous acid, allowed it to remain a short time, then removed it, after some few treatments the red color of the surface due to the columnar epithelium became a normally pale pink color. The speaker had seen this in many cases. Cases had been recorded where this experimentation had been carried so far that microscopic sections of the tissues were made before the pyroligneous acid had been applied, and again afterwards, showing that stratified epithelium had formed over these places.

It seemed to the speaker that we were too much limited by the methods of investigation which had thus far been employed, that the chemical side had been left out entirely. Observers had examined these cases histologically and morphologically to the limit; they had built theory after theory on morphological and histological bases, leaving out of consideration the possible chemical influences toward the investigation of which the natural processes ought to have led long before. He was referring now to those cases of metaplasia of organs or tumors which were originally covered with columnar epithelium, and in their continued growth became covered with stratified epithelium. He had removed a few weeks ago a polypus of the uterus from the inside of the uterus, the pedicle of which was attached to the inside of the uterus, so that he felt certain that originally the polypus must have been covered with columnar epithelium. He had found the apex of the polypus covered with stratified epithelium investing completely the part that was hanging out of the vagina exposed to the air. He had made the same observation on hemorrhoidal tumors coming out of the rectum, and hanging out of the anus. One could frequently make a diagnosis of cornification of hemorrhoids macroscopically, because on the tip of the hemorrhoid one could see a white spot, whereas the basal part of the hemorrhoid, the pedicle, was pink. He said there was another way in which stratified epithelium developed on organs where it was not originally found. He had removed a patent thyro-glossal duct. The duct had an opening on the outside where the columnar epithelium came in contact with the stratified epithelium. In this duct he was enabled to follow up the stratified epithelium with horny layers near the skin, to about the length of two centimeters into the duct. This was the same as Dr. Fütterer had mentioned in abscesses. Here there were influences about columnar epithelium which were not usually present, that is, exposure either to the air, or secretions which did not usually surround the epithelium. Taking the case of polypus projecting into the vagina, it was surrounded by the sour vaginal secretion, whereas the secretion inside the uterus was not sour. If a polypus projected more, there was exposure to air. There were processes of disease which sometimes influenced and favored the formation of stratified epithelium. For instance, he had found stratified epithelium in the vas deferens which was covered throughout with columnar epithelium in a case of tuberculosis of the vas deferens and seminal vesicles.

Dr. Fütterer said that Ziegler had found the same thing in tuberculosis of the urinary tract.

Dr. Ries stated that his remarks had reference to the vas deferens; he did not know about the urinary tract. With reference to ozena, mentioned by the essayist, in the cases of stratified epithelium in the body of the uterus, which the speaker had seen, they were also characterized and distinguished by a pronounced fetor. This observation had been made repeatedly, that where the horny epithelium was exposed to infection, it favored the formation of a disagreeable odor, probably because of the disintegration of the horny material. In carcinoma of the uterus, where stratified epithelium was found in the body of the uterus, he had found in the lymphatics belonging to the uterus, which were removed at the operation, glandular ducts which had since been the bone of contention among gynecologists who had been examining these glands microscopically. To explain such ducts, it might be said that the carcinoma of the uterus originated in the glands; that it had made glandular metastases in lymph nodes; these metastases looked like tubular glands, whereas in the uterus itself they had progressed to a different formation, so there would be metaplasia in the uterus and the original type of epithelium in the lymph nodes. The question had become more complicated recently, since it had been found that such glandular ducts in the lymph nodes might be caused by simple inflammatory processes.

The question of metaplasia arose again with regard to stratified epithelial carcinomas, many of them with horny products of the uterus. Quite recently he had seen a case of stratified epithelium carcinoma of the body of the uterus in which that diagnosis had been made and on careful examination he thought it was a carcinoma, originating in the columnar epithelium in the uterus, with considerable metaplasia, where the epithelial cells piled up and coalesced, showing many changes of growth that carcinomatous cells were liable to show. It was hard sometimes to say whether a

uterine carcinoma was stratified epithelial carcinoma originally, or stratified from misplaced epithelium, or whether it was ordinary columnar epithelial carcinoma with metaplasia. He had seen carcinoma of the vaginal portion involving the wall of the uterus, leaving the cavity of the uterus entirely free, but the whole cavity was lined with stratified epithelium, not connected at all with the stratified epithelial carcinoma in the wall.

He had observed metaplasia in the uterus in two cases, commonly called ichthyosis uteri. One of them was a woman over fifty years of age, upon whom he operated and extirpated the uterus. He made one curettement and found stratified epithelium. He found no pegs of epithelium going down deep, but the foul-smelling discharge and hemorrhages continued, so that he extirpated the uterus. He found stratified epithelium in the uterus in a case of puerperal infection in a young woman, not extending very high up, but reaching above the internal os. He had found metaplasia in the tube, particularly in tuberculosis, with distinct stratified epithelium. With all these possibilities, he thought it was going too far to assume that every patch of stratified epithelium surrounded by columnar epithelium, or columnar epithelium surrounded by stratified epithelium, must be an aberrant embryonal remnant. He thought the profession were not considering sufficiently the inherent abilities of the cells, and experimentation of the kind carried out by Dr. Fütterer, which would lead to final results, was very much needed. There were many other questions that naturally came up in connection with metaplasia, but the author simply desired to conclude by congratulating Dr. Fütterer on his interesting findings.

Dr. Benton B. Turck stated that when he was a student in Berlin he saw a very interesting case in the nose and throat clinic of Professor Fraenkel, of pachyderma of the vocal cord, the diagnosis having been confirmed by the Professor himself. The patient was a woman who had had frequent injections of iodine and of weak nitrate of silver solutions into the larynx some time before, and the question was raised whether this had not a good deal to do with the origin of the pachyderma of the cord. The woman was markedly anemic, which point was also brought out as a contributing effect, the anemia causing this pachyderma. But the work done by Dr. Fütterer showed that there was a trauma produced first, and in the center of this growth metaplasia occurred. One was almost compelled to accept the findings of Dr. Fütterer as a true metaplasia. In this case I report of pachyderma of the vocal cord chemical trauma undoubtedly played the important rôle. It was supposed to have been the starting-point of the pachyderma in the presence of anemia. One realizes how variable clinical conditions might be, but in the work of Dr. Fütterer one had the absolute experimental proof in the removal of a section, showing the ingrowing of normal glandular tissue and springing almost spontaneously from the center of this was the development of metaplasia.

Dr Fütterer, in closing the discussion, said that the influence of air, as mentioned by Dr. Ries, was a very important factor. In the case he had mentioned of Pollack, there were metastases from cylindrical epithelial carcinoma of the stomach, with squamous epithelial metastases in the lung. He (Pollack) also spoke of the influence of air favoring such changes. Dr. Fütterer thought friction had a great deal to do with the formation of this metaplasia in the most prominent part of the stomach. The mucous membrane was very much thickened and prominent, and there must have been considerable friction between those parts and the food.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, April 7, 1904.

The President, Dr. R. C. Norris, in the Chair.

(Continued from Page 432.)

New Modification of Operative Procedure for Retroflexion of the Uterus.—The author of this paper is Dr. E. E. Montgomery; it was read by Dr. John M. Fisher. This is a modification of the operation devised by Ferguson, of Chicago, but to the author's view his method comes nearer securing the desired result than any other he has yet selected. The writer condemns the operation of extraperitoneal shortening of the round ligaments or even the operation of Goldspohn. The method described by the author is one that is very readily performed through a single incision. It affords splendid opportunity for examining and treating the diseased conditions in the pelvis, and gives a fair measure of assurance of the retention of the uteras anteposed. Moreover, it is an operation which uses the natural forces of the uterus and does not add additional band of adhesions within the peritoneal cavity which may be a source of danger to the patient the remainder of her life, as does the operation of ventrosuspension. Furthermore, in the procreating women there is no positive assurance that the band formed in ventrosuspension will not be a source of distress and danger during the progress of her gestation. Besides, it also becomes a source of danger from loops of intestine slipping between it and the fixed uterus becoming strangulated. The author then describes the operation devised by Gilliam and Ferguson, which consists in making the median abdominal incision and drawing and securing the round ligaments through stab wounds in the recti muscle. Then the peritoneum external to the round ligaments is gathered together with a pursestring-like suture and tied. This closes completely the space between the round ligaments and the uterus, therefore prevents the intestine slipping between them. The author's modification of this operation is as follows: The abdomen is opened by median incision. The round ligament is picked up 1½ inches from the cornua of the uterus and a ligature is passed beneath it. Both ends of this ligature are carried by a Deschamps needle through an opening in the peritoneum anterior to the round ligament, to the parietal surface and beneath the parietal peritoneum to a point about the outer margin of the rectus muscle, where it is carried through the peritoneum, muscle and aponeurosis. The ligament on the opposite side is treated in a similar manner. The projecting loops of the ligaments are fastened by sutures to the aponeurosis, the final ones being passed in such a way as to decrease the size of the opening through which the loop was brought. The advantages he claims for this operation are as follows: The womb is maintained in an anterior position; it affords mobility to the organ; it introduces no adhesions nor extraneous material within the abdominal cavity and yet affords structures which will undergo hypertrophy and involution should the woman become pregnant. Moreover, it is of advantage in cases in which there is a tendency to prolapse of the ovary and tube as the relation of the retracted broad ligament to these organs forms a shelf upon which they are more likely to rest. He claims that it is also of service in cases of femoral hernia in that it decreases the directness of the pressure of the intestines on the femoral opening.

Dr. B. C. Hirst, in discussing Dr. Montgomery's second paper, remarked that his experience shows a vast majority of tubal pregnancies bleeding in this way as a tubal abortion, a proportion of nine out of ten at least.

Recent histological examinations explain why this is so. As has been said, the syncytium of the chorion villi or trophoblast eat into the blood vessels of the tubal mucosa. The bleeding comes from the inner wall of the tube, the blood is effused into the lumen of the tube and it has obviously escaped into the abdominal cavity from the abdominal ostium of the tube. In regard to the so-called rupture of the tube in tubal pregnancy; in looking over his whole collection of 68 specimens removed by operation, he doubts if he has a single case in which there has been an actual rupture of the tube in tubal pregnancy from distension. By a process of erosion, the syncytium eats its way to the peritoneal coat, which may then rupture or more likely is eroded like the rest of the tubal wall.

Dr. F. H. Maier, in discussing Dr. Montgomery's third paper, said that he had seen this operation performed quite a number of times, and it is surprising with what ease it is done and in what little time. As Dr. Fisher says, it is simply grasping the round ligament, throwing a ligature around it, making an opening in the peritoneum and carrying it subperitoneally to a point in the lower part of the rectus muscle parallel to the abdominal wound. It can be done almost as quickly as a ventrosuspension. The obstetrician knows that the round ligament and the peritoneum in time, even if they are somewhat distorted and bunched up, will gradually reassert themselves, as is seen in the changes that occur incident to pregnancy. It has distinct advantages over the Gilliam-Ferguson operation, in which, so far as Dr. Maier has seen of that procedure, the greatest trouble is in closing off the vestico-uterine pouch so that there will be no pressing of the intestines around the ligaments when they are drawn up into the lower recti incisions. It is possible to get nearer to the bladder and the peritoneum is bunched more than in this procedure of Dr. Montgomery. In this subperitoneal method there is no secondary suturing and no false ligaments in the peritoneal cavity to predispose to ileus. In displacements of long standing the tubes and ovaries are prolapsed with elongation. Many of these cases need not only suspension of the uterus but of the ovaries as well, and this operation is of advantage in such cases. Of course, as Dr. Montgomery says, it requires time to ascertain the results. It should not be judged hastily. In the Gilliam-Ferguson operation a good many patients returned, complaining of distress in the bladder. This might be due to the intrapelvic peritoneal suturing. Montgomery's method obviates that difficulty and in many ways is a most advantageous procedure.

Dr. P. Brooke Bland said he had no further remarks to make on tubal menstruation or on uterine hemorrhage. He does believe that this operation, devised by Dr. Montgomery, has distinct advantages. The particular advantage is that one uses the strong portion of the round ligaments. It is the only operation upon the ligaments that has this value. In the other operations one utilizes the portions of the round ligaments just as they leave the peritoneal cavity and they are very thin and weak in this region, and, indeed, sometimes cannot be found. Moreover, if shortening of the round ligaments by Alexander's method is contemplated, one has to make two incisions, and being an extraperitoneal operation any diseased condition could not be recognized or treated. Then, too, one may have sloughing of the round ligaments as they leave the abdominal cavity. These may then fall back and carry infectious material with them into the peritoneal cavity. Dr. Bland believes that by this operation, described by Dr. Montgomery, the uterus is successfully retained in a forward position. He does not feel that any operation on the outer portion of the round ligaments will maintain a chronically retrodisplaced uterus in an ante position for any length of time.

Dr. J. M. Fisher said that unfortunately patients are lost sight of after operation. It is difficult, therefore, to determine the value of any given procedure for the restoration of the uterus to its normal position. The question after all is, whether a displaced uterus, in a given case, from a clinical standpoint, is responsible for prevailing symptoms. There is no doubt in his mind that very many never give rise to symptoms, so that, even if the uterus is replaced, there is no change in the condition of the patient. For example, a patient was sent to the Jefferson Hospital to-day suffering from Jacksonian epilepsy. The family physician had found a backward displacement of the uterus and attributed the epilepsy to this condition. The displacement was easily corrected bimanually, and it was quite evident that the epilepsy bore no relation to the displacement. Dr. Fisher has seen most of the procedures that are practised for the correction of backward displacements of the uterus, and this operation, done by Dr. Montgomery, had impressed him very favorably. He has had a number of these operations at the Jefferson. He personally had experience in one case, but the operation was not performed with the same ease as Dr. Montgomery does it now; but Dr. Fisher is sure that after one has mastered the technic it can be done expeditiously. As Dr. Bland has said, the best part of the round ligament is used for the purpose. There are no raw surfaces left in the abdomen after completing the operation. The buttonhole opening in the broad ligament is closed by the round ligament and after this has been fixed to the fascia of the rectus, the anatomical relation of the uterus to surrounding structures is practically that of the organ under normal conditions.

Dr. Norris asked how much puckering there was of the broad ligament after the round ligament has been drawn through and out of the abdominal wall.

Dr. Fisher said that there is some shortening of the broad ligament. As the round ligament is drawn through its anterior leaflet it has some influence upon the tube and may bring about a flexed condition of this structure. As Dr. Montgomery has said, when there is a prolapsed condition of the ovaries and tubes it brings these structures into more favorable positions. A shelf is formed on the posterior aspect of the broad ligament on which the ovary rests. Dr. Fisher has not seen any of the patients after the operation, and is therefore unable to judge of the permanency of the results, but his present impression is that it presents very distinct advantages over every other form of round ligament operation.

Dr. Barton Cooke Hirst made these exhibits: (1) Ehrenfest's Pelvimeter; (2) Schatz's Metranoicter with Modification; (3) A Peculiar Neoplasm in the Puerperal Uterus, Probably of Inflammatory Origin; (4) A Fibroma of the Ovary Completely Calcified; (5) A Report of Experience with the Menge Pessary; (6) Photographs of Vaginal Cyst Stimulating a Cystocele.

(1) Dr. Hirst purchased Ehrenfest's pelvimeter after reading a description of it by its inventor. It is a scientific apparatus enabling one to do what was heretofore impossible in pelvimetry; to draw a diagram of the pelvic shape and size on a sheet of paper outside the woman's body. It gives a graphic representation of the size and shape of any pelvis that one desires to measure. One is not only able to take the anteroposterior but the lateral measurement as well. He thinks it is a useful instrument to have in all large lying-in hospitals where this work should be done in the most scien-

tific manner with the aid of an assistant experienced in pelvimetry. It is a difficult instrument to handle on account of the water level which enables one to keep parallel the lines drawn. Unless the lines are kept parallel the marks do not indicate the true size and shape of the pelvic cavity. It would not be practicable in ordinary private practice. With this instrument is another which Ehrenfest calls his kliseometer, an apparatus for measuring the angle of the pelvis. It is much easier to manipulate than the pelvimeter. Its use is only worth while, however, in very important cases of pelvic deformity, like some extreme examples of rachitis or spondylolisthesis. It is not an instrument suited for the every day use of a general physician.

(2) This instrument has interested Dr. Hirst greatly of late. It is called the Schatz's metranoicter. In looking over German literature he finds a disposition to condemn it. My attention was attracted to it by an article in the *Journal of Gynecology and Obstetrics for the British Empire*, in which an English surgeon said he had found it all that the inventor claimed. This influenced me to give it a trial. Dr. Hirst is pleased with it and believes it will prove an indispensable part of the gynecologist's armamentarium. The profession knows that there are many cases in which one would like to palpate the interior of the uterus, and also knows how difficult it often is to do it. Dr. Hirst has frequently tried to make a digital examination of the uterine cavity after using the ordinary branched dilators, but has usually failed. Uterine tents of sponges, laminaria and tupelo do secure very good dilation, but they are so dangerous that their use is scarcely justifiable. With this metranoicter in place twenty-four hours the forefinger can easily be inserted in the fundus. He has used it in thirteen women; in four for diagnostic purposes; in each it was possible to palpate the interior of the uterus with the utmost ease. If there is anything in dilation of the cervix at all, there must be more in this thorough and permanent kind of dilation than in any other that has heretofore been employed. He has used this instrument nine times for dysmenorrhea and sterility, in the cases in which branched dilators had been used, and he is pleased with the result. Some of these cases were the most severe types of dysmenorrhea; they have all been relieved, one or two in quite a remarkable manner. The operation is begun in the ordinary way by using three branched dilators: (1) Baer's modification of Goodell's two-branched dilator; (2) Wathen's heavy dilator; and (3) the four-branched Cleveland dilator. With the Baer instrument he dilates as much as the instrument allows; with the two-branched dilator an inch and a quarter; with the Cleveland, within 10 mm. of the highest capacity of the instrument; then the metranoicter is slipped in and left in the uterine cavity twenty-four hours. Dr. Hirst believes that this method of dilation will have a widespread use. It occurred to him, however, that Schatz's metranoicter might be somewhat improved, and he has had an instrument-maker make a four-branched instrument instead of the two-branched. He has used the modified metranoicter in one case, and at the end of twelve hours had the widest dilation of the cervical canal that he had ever secured by any plan of artificial dilation. He should have been disposed to criticize this instrument by asking whether it did not occasion unendurable pain. Of the thirteen cases in which it was used there was complaint on only two of pain, and these women, hysterical and neurasthenic, would have complained of pain at its very suggestion, so he thinks the profession may consider the method painless. He could not well dispense with this instrument. It enables him to do safely what he has never been able to do before, and it will, he believes, have a wide field of usefulness in practice.

(3) The next exhibit is an illustration of a case which Dr. Hirst thinks must give the profession serious cause for thought. His predicament in this case was one in which any one may find himself occasionally. He was called to see a woman who had been bleeding profusely for four days. She had been delivered at 6½ months, ten days before, and had had several hemorrhages during pregnancy. She was transferred to the hospital in an exsanguine condition. She was brought before the class in a clinic at the University, and served as a text for a lecture upon hemorrhage in the puerperum. The attention of the students was called to its possible causes, including malignant growths, but they were warned to think of the commoner causes first, and of malignancy last of all, as the rarest. On exploring the uterus, however, with curette forceps, in addition to placental fragments, material was removed of a brain-like consistency, such as is obtained from a case of adenocarcinoma. It was submitted to three different pathologists. They all agreed that it was exceedingly suspicious. One made a diagnosis of coritoepithelioma; another concurred, but with some reservation. The third disagreed, but admitted the possibility of malignant growth. They all recommended hysterectomy as a result of their study of the specimens. The uterus was accordingly removed. A neoplasm is shown, not at the placental site, and apparently of an inflammatory nature. It showed round-cell and leucocyte infiltration, with necrosis. There is no infiltration or hyperplasia of cyncytial cells, though the scrapings showed this plainly. It is a question whether it was a localized barrier against an incipient chorio-epithelioma. This case illustrates the difficulties in the diagnosis of chorio-epithelioma, before the disease has advanced to an inoperable stage.

In all cases of retained placental fragments and endometritis after labor, there is likely to be syncytial hyperplasia and infiltration of the myometrium by syncytial cells. How can one tell when the physiological limit has been passed and epithelial overgrowth has become malignant? When a large, vascular, friable mass has developed in utero, breaking down under the finger, and exhibiting a vast overgrowth of the syncytium, the diagnosis is plain enough, but how to make it in the earliest stage of the disease, he confesses he is at a loss; and yet, in no variety of malignant growths in the uterus is an early diagnosis so desirable. The mistake must occasionally be made, in the present stage of our knowledge of doing hysterectomy for what is regarded to be a malignant growth, when malignancy is not yet clearly established. The condition is a rare one and the dilemma does not often confront the profession, but when it does, he thinks one may feel puzzled and must acknowledge that a mistake is liable to be made. The patient in this case made a perfect recovery.

(4) The next specimen is an interesting one, of fibroma of the ovary. It has undergone complete calcification, and has the appearance as well as the feel of a cobblestone. The diagnosis before operation was calcification of a superitoneal fibroma. There was no ascites. It is an interesting question, whether calcification prevents ascites or not. The woman had suffered from the mechanical "insults" to surrounding structures from this freely mobile, stony-hard tumor in the abdomen. She made a good recovery.

(5) The next exhibit is Menge's pessary for prolapsus uteri. Certain women cannot or will not be operated on for prolapsus, and the task is imposed on the profession of keeping up the utera by some mechanical support. Dr. Hirst supposes, like most of the mem-

bers, he has tried every device in the instrument-makers' shops with more or less dissatisfaction, until he used this pessary of Menge's, described in the *Centralblat für Gynekologie*, a few months ago. He has had an opportunity, lately, to use the support with unlooked-for good results in some difficult cases. One woman had an enormous total prolapse of the uterus with severe pruritis vulvæ, the result of diabetes mellitus. She had more than five per cent. of sugar in the urine and was over sixty-five years of age. An operation would naturally have been unjustifiable. For the first time in several years the uterus remains at a normal level within the pelvis, the woman is comfortable and her pruritis is nearly cured. In short, the pessary has been a perfect success. In another case of total prolapse the woman had been operated on twice by other surgeons with complete failure. She positively declined another operation. In her case also the result with Menge's pessary has been satisfactory. The principle of the pessary is that it is kept in a transverse position in the vagina by the projection below somewhat on the principle of the fin keel of a boat. Several devices with this end in view have been proposed, but Dr. Hirst has found none so satisfactory as Menge's. The patient should be instructed to remove the pessary every night or every other night and to reinsert it in the morning. Its removal is facilitated by the detachment of the projection, which should be joined to the ring before the instrument is reinserted. Unless the pessary is removed at frequent intervals it has the disadvantage of all ring pessaries; it irritates the vaginal walls and causes ultimately extensive ulceration.

AMERICAN PROCTOLOGIC SOCIETY.

Sixth Annual Meeting at Atlantic City, June 8 and 9, 1904.

The President, Wm. M. Beach, M.D., of Pittsburg, in the Chair.

Things of Specialism and of This Society That Make for Optimism.—This was the text of the presidential address, and was a thoughtful and well-considered argument in support of specialism in general and of proctology in particular. He pointed out that the favorable recognition which had been accorded this specialty was largely due to this Society, and that as a direct result, though only six years old, the advertising charlatan had practically disappeared. The high type of men composing the membership was alluded to, and the continued exercise of careful circumspection in admitting new members advocated.

Surgical Treatment of Prolapse of the Rectum.—This was the subject of remarks by Dr. J. M. Mathews, of Louisville, in which he reported excellent results from drawing up the colon and suturing it to the abdominal wall. He had resorted to the method in a number of cases and believed the operation, colopexy, worthy of more general adoption.

Treatment of Pruritus Ani With the Roentgen Rays.—This subject was discussed by Dr. J. R. Pennington, of Chicago. From an experience covering a period of several years he had reached the conclusion that the X-rays were a valuable therapeutic measure in certain obstinate cases in which no cause for the pruritus is discoverable, and in which the secondary changes in the parts affected are most marked. He had succeeded in a number of instances in effecting a cure after every other form of treatment had failed.

The Present Status of the Treatment of Cancer of the Rectum.—This was the title of a paper by Dr. Lewis H. Adler, of Philadelphia. He considered four methods of treatment: (1) the X-rays, (2) radium, (3) extirpation, (4) colostomy. Speaking from his own experience he condemned both the first two mentioned, the X-rays, as aggravating the disease and apparently hastening death, the radium as being non-effective. With reference to extirpation he said that cancer of the rectum, at the stage usually discovered by the surgeon, is far less amenable to operative treatment than cancer occurring elsewhere; that extirpation, even when thorough, is followed by cure in only a small percentage of cases, owing frequently to prior metastasies; that the danger attending excision of the growths situated above the lower two or three inches is very great; and that the results as to freedom from pain in successful cases are usually far from satisfactory. He personally had been unable to advise excision in more than five per cent. of cases. Colostomy the author regarded a valuable palliative operation, the patient living in comparative comfort an average of three to four years. Personally he does not advise colostomy as early now as formerly.

The Flexible Rectal Tube.—This instrument was condemned by Dr. S. T. Earle, of Baltimore, as impracticable and of limited utility. His investigations of the subject had led him to conclude that as ordinarily employed by nurse or patient, the instrument curls upon itself in the lower rectal chamber and very rarely enters into the sigmoid. This difficulty may be overcome in a measure by attaching nozzle of fountain syringe to tube and allowing enough water to enter the bowel to distend it in front of advancing tube. In inexpert hands the instrument is capable of harm and except in the hands of the physician himself, the writer thought it should give place to the ordinary anema nozzle and elevation of patient's hips, by which method the same results can generally be obtained.

Poly-adenomata of the Rectum.—Dr. G. B. Evans, Dayton, O., presented this paper, in which he referred to the comparative varity of the disease and emphasized the importance of early and complete removal of the tumors, their tendency to undergo malignant changes being the chief danger. With the more general employment of instruments of precision in rectal examinations the writer predicted that polypi would be more frequently encountered in future.

Some Observations on the Treatment of Rectal Diseases.—Dr. W. L. Dickinson, of Saginaw, Mich., spoke of the great prominence diseases of the rectum had gained in the past 25 years. When he was a student the entire subject was disposed of in one lecture by the professor of surgery, "piles," being the only disease alluded to. Improvements in the office treatment of these conditions were discussed at some length, the author showing that it is possible in a large number of cases to do good, thorough work without general anesthesia and confinement of patient to bed.

Rectal Valves with Report of Operative Cases.—This was the title of an essay by Dr. L. J. Krouse, of Cincinnati. The author discussed the indications for valvotomy and endorsed it as a justifiable operation in properly selected cases, reporting a series of cases in which great and permanent benefit had followed its performance.

Treatment of Simple Rectal Fistula by Excision and Suture Without Cutting the External Sphincter Muscle.—Dr. Howard A. Kelly, of Baltimore, read this paper, in which he described the technic of an operation devised by himself and successfully employed in a number of cases. The procedure is applicable only when the fistula is simple and direct and consists of dissecting out the tract, beginning at the external opening. The rectal orifice is then carefully excised through the

wound so as to make a transverse opening parallel to the sphincter fibers. The wound is then closed by interrupted silkworm-gut or silver wire sutures, taking care to draw the circular fibers together above and below the rectal orifice.

Sterile Water Anesthesia in the Radical Treatment of Rectal Diseases.—This was the subject of a paper by Dr. S. G. Gant, of New York. In the author's opinion the hospital, general anesthesia, and confinement to bed constituted a routine, which, as applied to rectal diseases, was both unnecessary and unjustifiable in most instances. For several years he had been seeking means to overcome these disadvantages. After trying various agents for producing local anesthesia he had abandoned them one after another because of toxic effects, hemorrhage, pain or non-effectiveness. Finally he concluded that the anesthetic effect of these agents was due rather to pressure than to the drugs employed and was led to try sterile water alone. This gave him the happiest results. He reported 320 cases operated upon by this method, which included practically every variety of rectal disease amenable to operative treatment. The results had been so gratifying that he heartily recommended that the method be given a trial by other surgeons.

Papers by Dr. Leon Strauss, of St. Louis, and Dr. A. Tierlinck, of Gand, Belgium, in the absence of the authors, were read by title.

Officers.—The following officers were elected, after which the Society adjourned to meet in Pittsburg, May, 1905: President, Dr. J. R. Pennington, Chicago; Vice-President, Dr. L. H. Adler, Philadelphia; Secretary-Treasurer, Dr. A. B. Cooke, Nashville. Executive Council, Dr. W. M. Beach, Pittsburg; Dr. S. G. Gant, New York, and Dr. G. B. Evans, Dayton.

BRITISH MEDICAL ASSOCIATION.[1]

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

(Continued from Page 427.)

SECTION ON TROPICAL DISEASES.

Some Fallacies in Finalities.—This was the title of the address of the President of the section, Brig.-Surg. Alexander Crombie. He spoke of the modifications brought about in the investigations of many tropical diseases and pointed out the fallacies of many currently adopted opinions.

Malarial Fevers.—The criticisms of clinicians have, on the whole, been favorable to the belief in the occurrence in hot climates of fevers of a continued type other than typhoid and malarial remittents, but the opinions of our laboratory confrères have been almost uncompromisingly opposed to it. In a conversation he had last year at Liverpool, one expressed himself as having found no evidence of their existence, and Leonard Rogers, in a paper which he read before the Medico-Chirurgical Society in May last year, was still more emphatic. Quite recently, however, opinions have been expressed more in unison with clinical observation, and he thought it would be profitable to examine the grounds on which the laboratory opposition rested. Notwithstanding official returns to the contrary, which show an overwhelming majority of admissions for malarial fevers, "ague" is not the most prevalent type of fever in any of the parts of India where he practised his profession. The commonest type of fever is what he has elsewhere called a "single-paroxysm fever." The paroxysm may be of a few hours or a few days' duration, but it is a single paroxysm, and has no tendency to recur. If it lasts a few hours it is called "ephemeral fever," if a day or two it is called "febricula," if several days it is known as "simple continued fever." These attacks of fever give no clinical evidence of periodicity such as is caused by the life-cycle of a parasite renewing itself at frequent intervals in the blood. He failed to find the malarial parasite in such cases, and they recovered without quinine. But since his paper was written these cases of a single pyrexial paroxysm have, nevertheless, been by many regarded as essentially malarial in their nature. Rogers sounds no uncertain note on this subject. He says they are all malarial, as shown by a microscopical examination of the blood and an analysis of the symptoms. Several of his cases, he says, had a typical tertian character, each of them showed the mononuclear increase of malaria, and they were each cured by quinine. But he does not say that he found the malarial parasite present in any of them; neither is the fact that they each recovered after quinine evidence that they were malarial in nature, because they are essentially fevers of a single pyrexial paroxysm, and recover equally well without quinine as with it. There remains the one evidence of the mononuclear increase, but as this can no longer be held to be conclusive of recent malarial infection, nothing remains to support the contention that these cases of fever of a single paroxysm are all of a malarial nature. Quite recently James wrote as follows: "It is certain that other fevers than malaria are often returned under the term 'ague.' In order to ascertain what proportion of the admissions were really due to malaria, a number of men admitted for this disease were examined in October, 1901, by Dr. Christophers" (that is, in Mian Mir, the most malarious cantonment in India, and at the most malarious season) "and in 40 per cent. of these malarial parasites were found. In the same way he examined a number of men admitted or detained for ague during September, 1902, before any quinine had been administered to them, and found malarial parasites in 45 per cent. of the cases examined. During this month, also, through the courtesy of Major Gordon Hall, R.A.M.C., no quinine was administered as medicine to a number of cases in which he had not found parasites. All of them recovered in from one to three days, without any quinine treatment, and from this and the fact that several examinations in each case failed to show the presence of parasites, he concluded that these cases of fever were not due to malaria, though usually entered as such in the returns." Similarly, writing in Bombay in February, 1904, Mr. Arthur Powell bears testimony to the same effect. Thus he says: "Slight fever, for which no specific cause has been detected by me, is not uncommon in Europeans who have been a short time in the country. He had failed to find any malarial parasites in many such cases, and to test the theory that these are malarial, with a sparse infection, he had withheld quinine to see if a relapse would occur; no such recurrence has taken place."

One can therefore conclude that a large proportion of the febrile attacks of hot climates must still be included in the terms "febricula" and "simple continued fever," and that the evidence that they are all malarial is inadmissible. He then took a form of fever which he had called "non-malarial remittent." This was a fever of considerable severity, duration and mortality, lasting on an average six weeks, if not fatal at an earlier period. He had never been able to find malarial parasites in such patients, and quinine sometimes pushed to the extreme dosage of 90 gr. a day (6 grams) was not only ineffectual, but obviously harmful. In the discussion that followed the reading of his paper at the Edinburgh

1 From advance sheets of the *British Medical Journal*, by courtesy to the editors.

meeting of this Association, it was contended by the late Dr. Hughes, and by Dr. Edmonston Charles, who was well acquainted with this form of fever in Calcutta, and who had also made a study of Malta fever, that this "non-malarial remittent" was in reality Mediterranean fever. Dr. Crombie had seen some twenty cases of Malta fever in the wards of the General Hospital, Calcutta, landed from a man-of-war which had come straight from the Mediterranean, and their clinical picture was different from his patients. His confidence was somewhat shaken when it was announced about the time of the Edinburgh meeting that the sedimentation test for Malta fever had been successfully applied to cases of fever from Dugshai and elsewhere in Northern India, and even in cases from Calcutta; and a short time ago it was announced that agglutination occurred in every specimen of blood sent from fever cases in Assam, and that, in fact, kala-azar was epidemic Malta fever—a theory which has now been abandoned. What, then, is this form of fever which he described as occurring in India under the name of "non-malarial remittent?" Rogers, in his paper, came to the conclusion that it did not exist, although at the beginning of his investigations he believed in its existence, and was stimulated to try to find its true cause. He was driven to the conclusion as the result of his study of continued and remittent fever, by modern blood tests, that only two forms of fever exist in Lower Bengal, at any rate, of long duration, namely, typhoid and malarial remittents. A considerable portion of the cases could be distinguished, he said, by purely clinical methods, and the remainder by the serum test or by the differential leucocyte count, in all but a very few cases. The so-called "non-malarial remittent" in natives was, according to him, shown by the serum test to be nothing but typhoid fever. Unfortunately for this pronouncement, the ink with which it was written was hardly dry when Leishman made the discovery of the bodies, now associated with his name, in the spleens of cases of fever from Dum-dum which were neither malarial nor typhoid, and cases of identical character associated neither with malaria nor typhoid have now been reported from Sylhet, from China, from Tunis, from Egypt and the Soudan, from Madras, where they form 7 per cent. of the total native admissions to hospital, and kala-azar, which Rogers strove to prove to be a contagious form of malarial fever, is now shown to be a form of "non-malarial remittent" associated with the same bodies.

He said he did not bring these points out as a parade of superior clinical sagacity. He made no such claim, for two reasons: first, because the knowledge that has from time to time to deal with cases which could be classed neither with typhoid nor malarial fevers was common property among clinicians of his day, before "modern methods" cast a doubt on the existence of what has habitually been called "non-malarial remittent," and it was only his fortune to voice this conviction; and secondly, because the clinical character of the cases associated with Leishman's bodies is very often apparently entirely different from that of the fever which, in his address of 1894, he described under that name. His object was to point out the fallacies which lay in the way of investigators, and turn them aside from the path on which some of them set out with a clear object in view, and which would, if pursued with more imagination and stricter logic, have surely led them to the discovery of the existence of this class of fevers which they have hitherto denied.

The fallacy, he said, was the fallacy of finality, the fallacy that every step made in advance is final and that every fact of medicine must be brought into line with it for the reason that there is nothing beyond. It is a fallacy which has mired the progress of medicine ever since it started on its journey. To go no further back than the middle of last century, we find that previous to that time there was only one kind of non-malarial fever, and that that was typhus. In vain did clinicians and pathologists point out, and none more clearly than Scriven, of the General Hospital in Calcutta, and Annersley, of Madras, in 1835, that there existed another type of fever of more insidious character and accompanied by ulcerations of the small intestine, which was clinically and pathologically distinct. It was not till fourteen years later, when Jenner's classical labors showed it to European practitioners, that they had ears to hear and eyes to see that the "typhoid" fever of the English, the abdominal typhus of the Continent, was a distinct pathological and clinical entity. But it was thought this step was final: every fever that was not malarial must be either typhus or enteric, and Mediterranean fever had to be included in one or other of these categories, and we accordingly find even Laveran, in the early editions of his great work on *Paludisme*, classifying it in this way, notwithstanding its striking divergence clinically from either malarial or typhoid fevers. Then came Bruce to show us that it was as distinct bacteriologically as it was clinically and pathologically from either. At last the end of everything was reached, and every fever that was not malarial or typhoid was Malta fever, as was maintained at the Edinburgh meeting, and in proof of this opinion came reports of serum tests from Upper India and Assam entirely corroborative of it, and it was clinched by the discovery of the clinical significance of the leucocyte count. Rogers was the great apostle of the leucocyte count, and his whole argument in the paper he read last year was based on the opinion that "by this means alone, in the great majority of cases, a correct diagnosis can be arrived at by the examination of stained blood-films with an ordinary high-power lens." He had arrived at finality; an increase of the percentage of lymphocytes indicated typhoid, and of the large mononuclears, malarial fever. The presence of the malarial parasite was of little comparative importance, and, in fact, he only found it in less than 25 per cent. of the cases he diagnosed as malarial by the differential leucocyte count. Further, he said: "I am far from disparaging the value of this method of investigation, and I use it constantly, but I use it with caution, because it has been found that the presence of an increased percentage of mononuclears is not confined to malarial infection. It has been found in the spotted fever of the Rocky Mountains, in the fever of trypanosomiasis, in black water fever, and in that associated with Leishman's bodies. It has indeed been abandoned by Rogers himself, for in a recent communication he says that 'if the new bodies are not a form of malarial organism, then it is evident that a large mononuclear increase is not diagnostic of malaria, but rather an indication of the presence of a protozoal as opposed to a bacterial invasion of the system,' and his whole argument as to the non-existence of a 'non-malarial remittent' fever crumbles before his own breath. But that is not all. Even if we admit that it is evidence of a protozoal infection, it is not incontrovertible evidence of an active or even recent protozoal infection. The question of the duration of the mononuclear increase after an attack of ague is one which is of the greatest importance in this relationship, and I have evidence that it may continue for a very considerable period. In a case of insomnia which I have now under observation the large mononuclears constituted 24 per cent. of the total leucocytes in October, 1903, and again in July, 1904, although the last

possible malarial infection was at Delagoa Bay in April, 1902, so that, apparently, this phenomenon may continue for over two years, and possibly much longer, and cannot, therefore, be regarded in a malarial country as evidence of present, or even recent, malarial infection, putting aside the consideration that it occurs in other febrile conditions.

Widal Test Not Conclusive.—It may seem hypercritical to apply similar reasoning to the arguments which have been brought forward to prove that this so-called 'non-malarial remittent' is nothing more than typhoid. I require something more than an increased percentage of lymphocytes, or even the Widal reaction, to convince me that enteric is a common fever among natives of Lower Bengal. It has yet to be proved that typhoid is the only fever in which an increased lymphocyte percentage occurs, and until that is done all argument founded on that assumption is a mere begging of the question, irrespective of Rogers' admission that it was absent in one-third of the cases so diagnosed by him. I must also demur to accepting a positive Widal reaction as conclusive of active typhoidal infection in any given case of fever in a native of Bengal. As with the mononuclear increase in malarial, or rather protozoal, infection, so the phenomenon of agglutination may occur under other conditions, and is often of long and indefinite duration. Though it is lost as a rule in a few months after an attack of typhoid, it may persist for twenty-five years, according to Horton Smith, so that any case of fever occurring within an indefinite period after recovery from this fever may give the reaction without any fresh infection by the bacillus of Eberth having occurred. It is even an unjustifiable assumption that a previous attack of typhoid fever is necessary for the manifestation of the reaction in natives of Lower Bengal who give no history of any fever which could be regarded as having been typhoidal. This is a point on which Freyer, of the R.A.M.C., was the first to sound a warning note. I am aware that the dilution he used was too low, and that healthy blood sometimes gives positive evidence of the agglutination in 1 in 12. I am also aware of the negative results obtained by Lamb, of Bombay, who used the sedimentation test, but I think it desirable to put on record those which I obtained in examining the blood of healthy natives of India living in London. I sent specimens of the blood of eleven such natives to Mr. Bokenham, Dr. Klein, and Captain Hayward Pinch of the Polyclinic, as I was in the habit of doing in ordinary clinical work unconnected with this inquiry. In six of these the result was entirely negative, but of these three were over forty years of age, two were natives of the Punjab, and only one was a young Bengali. The remaining five were young natives of Lower Bengal or Assam, studying law or medicine in England. When not otherwise stated the dilution was 1 in 50. Of these two gave a marked reaction in twenty minutes; three gave the reaction slowly, showing many clumps in half-an-hour, two of them giving a marked reaction in dilutions of 1 in 30. In two instances the blood was re-examined after an interval of six months. In one there was 'distinct partial clumping in thirty minutes, better still in one hour in a dilution of 1 in 20' (Klein). In the other there was no sedimentation with a typhoid culture, 'but in a hanging-drop preparation made with the typhoid culture a distinct loss of motility—as contrasted with a control slide—was noticed in three hours and at the end of five and a half hours all movement had ceased, but there was not the slightest attempt at agglutination. This certainly does suggest that the blood contained some substance inimical to the vitality of the typhoid bacillus' (Pinch). None of these young men had a history of fever which could be regarded as indicating recent typhoid infection, and yet there were present in their blood substances which are regarded in ordinary laboratory work as indicative of present or recent typhoid infection, and I think we must therefore accept with reserve the opinion formed on the serum reaction alone, that typhoid fever is a common form of fever in natives of lower Bengal, in the face of these results and the experience of many medical officers who have regarded it as rare, an experience grounded not only on clinical observation, but on necropsy."

In his address of 1894 he said he had spoken of Bastard Typhoid, a continued fever, which ran the course of a mild typhoid, of from three to four weeks' duration, but which had none of the clinical symptoms of that disease. It had been recognized as a peculiar type in all the larger towns of India, where it was known by the local names of "Calcutta fever," "Bombay fever," etc. In the absence of specific evidence that it was no other than typhoid, clinicians declined to give it this name, although they treated it as such. He provisionally called it "urban fever" in 1894, but is now prepared to regard it as a peculiar form of typhoid, and in my paper in the *Encyclopedia Medica* had suggested the alternative name of "Bastard Typhoid." His reasons for advancing it to this category are that in one case which he had an opportunity of examining before he left Calcutta he obtained the Widal reaction, and as this is a fever of Europeans, the same objection does not exist to accepting this evidence as it does in the case of natives. Rogers also states that he found this reaction in every case of continued fever in the wards of the European General Hospital. It would have been more satisfactory if he had sorted the cases clinically, so as to have been able to make it quite clear that his enumeration included cases of this type, for the fact that they conform to the serum reaction of typhoid fever in no way alters the fact that they exist as a distinct clinical type. It has been demonstrated that there are several types of enteric fever, and a form which does not give the serum reaction in any period of its course has been pointed out under the name of "Paratyphoid." And he thought that the distinct clinical type which is so well recognized in India, and which he has called "Bastard Typhoid," ought not to be dismissed because it gives the serum reaction, but its peculiar clinical features rather mark it for more exact research. His experience in connection with the typhoid fever of the South African war, which showed several very distinct deviations from the ordinary classical enteric of the text-books, namely, the often copious eruption, the frequency of thrombosis and of muco-enteritis as a sequela, has led him to think that typhoid fever is generally a mixed infection, the symptoms and severity varying with the amount and quality of the mixture, and it is not impossible that the peculiar type which occurs in the large cities of India may turn out to be a pure infection with Eberth's bacillus, and may thus form the bed-rock on which the more classical cases are built up by additions of other intestinal flora.

(To be Continued.)

Medical Society of the State of New York.—The following have been appointed the Business Committee of the Medical Society of the State of New York, by the President, Dr. H. D. Wey: Dr. Henry Flood, of Elmira; Dr. A. Edward Davis, of New York, and Dr. Leo H. Neuman, of Albany. Those interested in the program of the next annual meeting of the Society, to be held in Albany January 31, February 1 and 2, next, will communicate with them, as they are charged with its preparation.

VOL. 85. NEW YORK, SATURDAY, SEPTEMBER 10, 1904. NO. 11.

ORIGINAL ARTICLES.

AN ANALYTICAL STUDY OF TWENTY-EIGHT CASES OF ARTHRITIS, WITH SPECIAL REFERENCE TO GOUT AND ITS TREATMENT.[1]

BY CHARLES C. RANSOM, M.D.,
OF NEW YORK;
VISITING PHYSICIAN TO THE CITY HOSPITAL.

THE prevalence of gout in this country has long been thought to be less than in the British Empire and the European countries in general. But an analytical study of the arthritides, which came under the writer's observation in the second medical service of the City Hospital during the months of November, December and January of this past winter, shows a considerable difference in statistics from those of other observers.

During the period of time just mentioned, 415 patients were admitted to the second medical service. Of these there were twenty-eight cases of arthritis, or six per cent. of the total number; 23 being males and five females. Of the 28 arthritides 12, or 43 per cent., were gout, this being 2.89 per cent. of the total number of cases admitted. Five of these were acute podagra, while the other seven were of the chronic type of the disease. Of the other cases there were five (18 per cent.) of rheumatic arthritis, or 1.2 per cent. of the total admissions, four acute and one chronic; five gonorrheal arthritis, one septic arthritis, one arthritis deformans and two cases of erythromelalgia.

The first thing that impresses one on reading over the foregoing statistics of these 28 cases is the relatively large incidence of gout. One would naturally ask in the face of this, if the diagnoses made were correct, and if the observations made were unaffected by personal bias—one of the greatest sources of error in work of this character. Let us go over the cases of gout a little more in detail and see if our classification is correct. The acute cases of gout were all classic, beginning in the metatarsophalangeal joints of the great toes with swelling, redness and pain which was worse at night, and with a sharp initial fever; all of these symptoms promptly subsided under the administration of colchicum. With these cases there is, of course, no opportunity for mistake in diagnosis, nor would we expect to find it in the acute forms, but it is in the chronic forms where the clinical history of the onset and development of the affection is typical neither of gout nor rheumatism, that we would look to find errors of classification, if any exist. A review of the seven cases of chronic gout will show, with perhaps two exceptions, that there was no possibility of a mistake in diagnosis.

[1] Read before the West End Medical Society, April 30, 1904.

Case III.—Male; patient complained of pain and stiffness in right instep, heel, and ankle. There was no history of injury or strain. The lameness on motion was extreme and incapacitated him for work. A thorough course of salicin had no effect upon the trouble, upon the administration of colchicin the joints promptly improved and the pain, soreness and stiffness disappeared.

Case VI.—Male; patient complained of pain, soreness and stiffness in both knees, both ankles and both feet. The knee joints were thickened, stiff, and with very limited motion. The ankle joints were also thickened and stiff. The metatarsophalangeal joints of both great toes were thickened, stiff and somewhat painful on pressure. Patient improved on colchicin and passive movements.

Case VIII.—Male; patient complained of pain in right knee, both elbows, metacarpal joint of right thumb and metatarsophalangeal joint of great toe. The affected joints were all red, swollen and inflamed. A previous attack one year ago began in the metatarsophalangeal joint of the great toes and came on at night. Patient responded promptly to the administration of colchicin.

Case XVIII.—Male; this case had marked deformity of feet, ankles, knees, hands and elbows from gouty tophi, there were also tophi on the ears. There can be no doubt of the diagnosis in this case.

Case XIX.—Male; the attack began in the phalangeal joints of the third and fourth fingers of the right hand, and the second and third fingers of the left, then involved the left wrist. The affected fingers of both hands were swollen and stiff, the inflammation having subsided. There was also a node on the flexor tendon of the third finger of the left hand with a beginning Dupuytren's contraction. The patient was kept on salicin for two weeks with no effect, but improved very promptly on colchicin.

Case XXV.—Female; patient complained of pain and soreness in metatarsophalangeal joints of both great toes, also in both knees and ankles. The affected joints were swollen, red and tender to touch. There was some crepitation in the knee joints. Attacks would often be precipitated by worry due to domestic trouble. Attack yielded very promptly to colchicin.

Case XXVII.—Female; patient complained of pain and stiffness in both knees and in metacarpophalangeal joint of right thumb. The knee-joints were thickened, swollen and painful, as was also the joint of thumb. There was considerable deposit about the thumb joint. Patient was put on salicin for five days with no effect; on colchicin she was up in four days.

Thus it will be seen that there are only two cases in which there could be the slightest possibility of doubt as to the diagnosis of gout. In *Case III* the pain and stiffness in the ankle, heel and instep began a month previous to admission into the hospital, and gradually grew worse without any inflammation or swelling until the patient was incapacitated. The short duration of the trouble, its insidious development without inflammation, and the fact that it did not respond to salicin, but did to colchicin, seems to show that the process was a gouty one rather than rheumatic. In *Case XIX*, the other one in which there might be doubt, the affection began in the phalangeal joints of both hands. At first it was thought that it might be the beginning of arthritis deformans, but as it subsided without the implication of other joints except the wrist, and was controlled by the administration of colchicin, the diagnosis of gout was made. Assuming that these two cases were not gout we still have in the series of 28 cases of arthritis a percentage of 35.7 of gout and 2.4 per cent. of the total admissions to the service, far more than the frequency usually given to that disease in this country.

Of these twelve cases of gout, ten were in men and two in women.

It is a very difficult matter in tabulating a number of cases in this fashion to know in just what manner to separate the acute from the chronic forms, especially when several of the latter have come under observation during and by reason of an acute exacerbation. In the classification of these cases no definite plan has been followed and the division into acute and chronic gout has been made in a purely arbitrary manner.

Quite as surprising as the high percentage of gout cases in the group of 28, is the relatively small number of cases of rheumatic arthritis. Only 18 per cent. of the total number were in this class, or 1.20 per cent. of the total number of patients admitted. Of these five cases four were acute rheumatic arthritis and only one chronic rheumatism. Indeed, this one was placed in the category of chronic rheumatism out of deference to the opinion of those who believe in the comparative frequency of this condition rather than because it was believed to be in any way rheumatic. This was *Case VII*, male, aged seventy years. This might just as well be called senile gout as chronic rheumatism, inasmuch as there had never been an acute attack of arthritis of any kind, but there had been a progressive stiffness and lameness of the muscles and tendons of the phalanges with no changes in the joint structures, all this being concomitant with senile changes in other parts of the body.

Gonorrheal Arthritis.—This class comprises 18 per cent. of the total number of cases of arthritis, an equal number with rheumatic arthritis. This relatively large number is not altogether surprising when one stops to consider the class of patients at the City Hospital, where these cases were seen. Four of them were in males and one in a female.

Septic Arthritis.—Only one case, 3.5 per cent. of the total number was in this class. This was *Case XXII*, female, whose joint trouble dated back some years to an attack of septicemia following a miscarriage.

Erythromelalgia.—There were two cases of this rather rare disease, and while strictly speaking not an arthritis, the cases so closely resembled a gouty arthritis they were considered as such on admission and for some time afterward.

Doubtful Cases.—Two cases are placed in this category. One of these came in from Bellevue, after the acute attack had subsided. At the time of admission there was a great deal of stiffness and some swelling in both ankles. The patient said the attack had come on ten days previously with great pain, swelling and redness of both ankles and attended with high fever. As the soreness and stiffness increased under administration of salicin but yielded very promptly to colchicin, it was thought there was a reasonable doubt as to its having been rheumatism, so it was classified as doubtful. The second case was one of an intramuscular node in the trapezius, whether of a rheumatic or gouty origin it was impossible to say.

Arthritis Deformans.—There was one case of this kind in a female. In the five cases of acute gouty arthritis the attack began in the metatarsophalangeal joints of the great toes in three, the palangeal joints in one, and the ankle in one. The joints to become ultimately affected were the instep, shoulder and chondrosternal joints in this order of frequency.

In the cases of chronic gouty arthritis the initial attacks began in the ankles in four, in the metatarsophalangeal joints of the great toes in one, in the knees in one, and in the phalangeal joints in one. The joints ultimately affected were the knees, metacarpophalangeal joint of thumb, instep, shoulders, elbows and wrists in this order of frequency.

In the four cases of acute rheumatic arthritis, the first manifestations were in the left ankle in two, in the left hand and wrist in one, and in both knees and both elbows simultaneously in one. The joints ultimately affected were the hands, shoulders and feet.

In the cases of gonorrheal arthritis the ankles were first affected in two, the hand in two, and the left knee in one. In all the cases there was a polyarthritis, and in one all the joints of both extremities were involved, as was also the spine with the production of a very marked kyphosis. In all these cases the arthritis followed closely upon the development of a gonorrheal urethritis, and in three of the cases there had been a previous arthritis, each one following a gonorrhea. The case with kyphosis had had three previous attacks. In all of these cases several of the joints had been affected at the same time.

In the one case of arthritis deformans the affection had existed for ten years. The first attack beginning in the feet had lasted three months. From that time on for several years there had

been repeated attacks, at intervals varying in duration from a few months to a year. With each succeeding attack more joints would become involved, until all the joints of both extremities became fixed, distorted and painful. The legs were flexed upon the thighs and the elbows fixed at right angles. All movements of the joints were painful, and in many of them there was a marked crepitus on motion.

The two cases of erythromelalgia, while not properly arthridides, are sufficiently interesting to warrant a brief description.

Case XI.—Male, aged sixty-five years, butcher. For twenty-five years had pain in metatarsophalangeal joints of both great toes, but more often in the left. Six months previous to attack was seized with vertigo and fell on the floor. The following day was unable to move the right leg. From that time to admission to the hospital was unable to walk (this was early in October). Since admission there was gradual improvement and some locomotion was possible. The feet were stiff and somewhat thickened, especially in the metatarsophalangeal joints of both great toes. The skin was hard, shiny and looked too small for the foot. The color of the skin was a dusky purple-red; both feet were cold to the touch. During the months of December and January a superficial ulceration appeared on the plantar surface of the right great toe. There was also a transitory glycosuria present.

Case II.—Laundry worker; ten months ago first had pain in feet. This would at times extend up the legs. Four weeks ago the pain in the left great toe became more frequent and intense, had to stop work. On admission the great toe of the left foot was swollen, red and painful, pain was much worse at night. While the appearance of the joint was typical of a podagra, the surface was cold to touch. After about three weeks in the hospital an ulcer appeared on the affected toe. There was no glycosuria.

Treatment.—The cases of acute gouty arthritis were put upon a milk diet, the joints were painted with what is called "joint special," a mixture composed of oil of gaultheria 1 dram, ichthyol 1 ounce, wrapped in cotton wool over which rubber protective or oil silk was held in place by a roller bandage. Colchicin 1-100 of a grain was given every two hours. If the bowels were affected by the colchicin it was given at longer intervals. As a rule the colchicin could be continued at two hour intervals for forty-eight hours or more. The inflammation and pain were usually controlled within this time, and after all acute symptoms had subsided the drug was continued at intervals of four hours until the patient was discharged.

In the chronic cases of gout the same method was employed if there was inflammation in any of the joints. The joints which were stiff were massaged and given passive movements, and the patients were directed to use the joints as much as possible. This is a most important thing to do, as the tendency of all these patients is to spare the joints and the liability to permanent stiffness and disability is thereby very much increased. There is no danger of setting up a new attack in a joint if the manipulations are begun after all inflammation has subsided. A very simple apparatus was employed which may be called a "teeter," and it was found to be most useful in limbering up stiffened knees and ankles. The "teeter" consists of a piece of board 21 inches long and eight inches wide. About three inches from the lower end another piece of board about ten inches long is fastened to the first piece at right angles by means of a bracket. Upon the shelf so formed the foot of the affected leg is placed, the longer board being in contact with the posterior aspect of the leg. The patient then sits in a rocking chair and rocks to and fro, thereby producing a greater or less amount of motion in the knee and ankle-joints. Very soon the patient becomes accustomed to the apparatus and can read while taking his exercise. It is an advantage over walking, as it not only keeps the weight of the body off the knees, but compels a much greater angle of motion. There is always a tendency on the part of a patient to fix the muscles so that the movement of the joint on manipulation is much more limited than is caused by the pathological changes in its structure. The use of the "teeter" eliminates this muscular rigidity and the movements of the joints are only limited by the actual structural changes. By persistent use these are to a great degree gradually overcome.

It has often been said that colchicum should never be used in chronic gout, because it would do no good, that by continual use the patient would become accustomed to it, and its effect would be lost in event of an acute exacerbation. Personal experience with it in chronic cases is entirely contrary to that opinion. It has been found to be of the greatest service in clearing up the joint symptoms in these cases, and when an acute exacerbation has supervened, its prompt effect in controlling the paroxysm has in no way been diminished. As an example of what it has accomplished in the writer's hands in chronic gout the following case is cited:

Case XIII.—Male; blacksmith; first came under observation three years ago, having suffered from gout for ten years, the last two years of that period he had been in the City Hospital. During the first six months of his stay in the hospital he had had repeated attacks affecting his feet, ankles, knees and hands, and had been confined to the bed off and on. During the remaining eighteen months he had been practically bedridden. At that time he was supposed to have arthritis deformans. At the time of admission to the second division of the hospital there was considerable inflammation of the toes, ankles, knees and hands. Wine of colchicum was administered to the point of tolerance. In the course of ten days the acute soreness had subsided, passive movements were then given. Within a month he was walking about the ward

TABLE OF CASES OF ARTHRITIS.

No. Case.	Sex.	Age.	Occupation.	Diagnosis.	Family History.	Previous History.	Mode of Onset.	Joints First Affected.	Joints Ultimately Affected.	Treatment.	Remarks.
1	M.	31	Laborer.	Acute rheumatic arthritis	Negative.	No previous sickness	Two weeks ago both knees and elbows became inflamed; had fever and profuse sweating.	Both elbows and both knees.	Elbows and knees.	Salicin; joint special.	Under salicin patient was able to sit up in three days. Soreness lasted in all eighteen days.
2	M.	51	Laborer.	Acute rheumatic arthritis	Negative.	Arthritis off and on for twelve years: fairly heavy drinker	Swelling, pain and inflammation in ankles eight weeks ago; came on at night.	Both ankles.	Left ankle.	Joint special.	No sweating with attack and coming on at night suggests gout.
3	M.	65	Mason.	Chronic gouty arthritis.	Negative.	Malaria forty years ago; had pains in joints at times.	Pain in right instep, heel and ankles; no redness or swelling.	Right instep, heel and ankle.	Right instep, heel and ankle.	Salicin for seven days; then colchicin; joint special.	No effect from salicin, prompt relief from colchicin.
4	M.	30	Laundry worker.	Erythromelalgia.	Negative.	No previous illness.	Occasional pain in big toes and feet, gradually extending up legs.	Both feet and big toes.	Both great toes; left worse.	Colchicin; dressing alumium acetate.	Appearance of both great toes very like acute gout; did not yield to colchicin; later ulcer developed on left great toe.
5	M.	39	Boatman.	Acute gouty arthritis.	Negative.	Similar attack two years ago.	Began with swelling and pain in phalanx of middle finger; three days later affected both great toes.	Phalanx middle finger; both great toes.	Both great toes.	Colchicin; joint special.	Yielded promptly to colchicin.
6	M.	55	Laborer.	Chronic gouty arthritis.	Negative.	Malaria twenty-five years ago; arthritis for ten years.	Pain in ankles and feet, off and on for ten years has affected knees and other joints.	Great toes, feet and ankles.	Toes, feet, ankles and knees.	Colchicin; joint special, "teeter" for knees.	After using teeter for some weeks, could walk about ward.
7	M.	48	Painter.	Acute gouty arthritis.	Father and brother had rheumatism	Syphilis twenty-five years ago; rheumatism at twelve years; several attacks of arthritis.	Began at midnight in ankle; twenty-four hours later in both big toes; joints inflamed swollen and painful.	Ankles; then big toes.	Both ankles; toes on left foot.	Colchicin; joint special.	All pain left in forty-eight hours; and was discharged from hospital in six days.
8	M.	45	Iceman.	Chronic gouty arthritis.	Father died of rheumatism.	Heavy drinker; syphilis fifteen years ago; arthritis for eight years.	Began in ankles, knees and elbow; later attack began in both big toes; coming on at night, with pain, swelling and inflammation.	Knees, ankles, elbow and big toes.	Right knee and ankle; both elbows metacarpophalangeal joint of thumb.	Colchicin; joint special.	Gradual improvement in all joints; considerable deposit about thumbs.
9	M.	33	Stableman.	Gonorrheal arthritis.	Negative.	Has had two previous attacks, each following gonorrhea.	One week after gonorrhea had subsided, left ankle became inflamed then went to toes, knees, shoulder and neck.	Knee, ankle, shoulder, back of neck.	Knee principally; also ankle, shoulder and neck.	Colchicin, salicin; joint special; etched urethra with nitrate of silver.	Colchicin and salicin had no effect; patient well and discharged after four etchings.
10	M.	27	Waiter.	Gonorrheal arthritis.	Negative.	Grippe ten years ago. No previous arthritis.	One month after gonorrhea both knees became red, swollen and painful.	Both knees.	Both knees; effusion in left.	Colchicin, salicin; joint special; etched urethra with nitrate of silver.	Colchicin and salicin had no effect. Soreness lessened after each etching; had three etchings.
11	M.	45	Laborer.	Chronic gonorrheal arthritis.	Negative.	Moderate beer drinker; had gonorrhea ten times; and last three followed by arthritis.	Left hand became red, swollen and painful after an attack of gonorrhea; extended to shoulders, knees, back.	Hands, shoulder, knees and back.	Practically all the joints; marked hyphosis.	Hot air baths; joint special; ichthyol bath; colchicin.	Hot air did no good; relief from ichthyol bath; some better with colchicin.
12	M.	39	Driver.	Gonorrheal arthritis.	Father had rheumatism.	Heavy drinker; acute rheumatism at age of twelve with iritis.	Four weeks after gonorrhea developed pain, redness, and swelling in right ankle, right wrists and both knees.	Right wrist, right ankle and knees.	Right wrist, right ankle and knees.	Joint special; irrigation of urethra with permanganate of potass.; passive movements.	Much improved under treatment; a little soreness left.
13	M.	46	Silk cutter.	Acute gouty arthritis.	Father had gout.	Moderate drinker; syphilis twenty-five years ago; gonorrhea.	Great toes became inflamed and painful at night, then went in fingers.	Great toe of right foot, three fingers.	Great toe of right foot, fingers.	Colchicin; joint special.	Prompt relief on administration of colchicin.
14	M.	43	Cook.	Intramuscular node in trapezius.	Mother had rheumatism.	Heavy drinker; gonorrhea three times. Syphilis fourteen years ago; rheumatism ten years ago.	Was drinking heavily; excessive pain developed in muscles of neck and shoulders.	No joints affected.	No joints; muscle of neck and shoulder.	Colchicin; deep massage over trapezius.	Relief from pain and lameness in a short time after massage.

TABLE OF CASES OF ARTHRITIS—Continued.

No. Case.	Sex.	Age.	Occupation.	Diagnosis.	Family History.	Previous History.	Mode of Onset.	Joints First Affected.	Joints Utlimately Affected.	Treatment.	Remarks.
15	M.	65	Butcher.	Erythro-melalgia.	Negative.	Has had attacks of pain in great toes for twenty-five years; glycosuria.	Pain began in great toes; has had it off and on for twenty-five years.	Great toes both feet.	Great toes both feet; ulcer on plantar surface of great toe.	Colchicin; tonics.	Appearance of feet similar to Case IV—No effect from colchicin. Patient has a transitory glycosuria.
16	M.	40	Tile-layer.	Acute gouty arthritis.	Negative.	Drinks heavily; and eight years ago had arthritis.	Pain, redness and swelling; began in great toe, right foot, then in chondro-sternal joint.	Great toe, chondro-sternal joint.	Great toe, chondro-sternal joint, left shoulder, node in left palm.	Colchicin, joint special.	Colchicin controlled pain; acted very severely on bowels.
17	M.	70	Watchmaker.	Chronic rheumatism.	Father and mother had rheumatism.	Stiffness and soreness of muscles for years.	No joints; general muscular stiffness.	.....	.....	Tonic.	No especial improvement; general senility.
18	M.	51	Blacksmith.	Chronic gouty arthritis.	Negative.	Rhinewine drinker, pretty freely; large meat eater; and arthritis for thirteen years.	First attack began in great toe of right foot, with pain, redness and swelling; then in left.	Great toe right foot; then left foot, ankles and knees.	All joints; large tophir on hands and feet.	Colchicin; joint special; ichthyol bath; massage.	Always got relief from colchicin; was also improving by ichthyol bath; iodide of potassium would always bring on an attack.
19	M.	27	Porter.	Chronic gouty arthritis.	Negative.	Moderate drinker; nine years ago attack in fingers.	Pain and swelling in fingers; then in hips.	Phalanges.	Phalanges, fingers, hip.	Salicin two weeks; colchicin; joint special.	Salicin had no effect; colchicin every four hours had no effect; colchicin every two hours promptly relieved pain and swelling.
20	M.	43	Driver.	Acute rheumatic arthritis	Negative.	Heavy drinker two former attacks.	Left hand and wrist became painful, red and swollen at night.	Hand and wrist; then elbows and shoulders.	Hand, wrist, elbows and shoulders.	Sod. salicylate, salicin; joints special; massage.	Yielded promptly to salicylates.
21	M.	53	Laborer.	Chronic gouty arthritis.	Negative.	Moderate drinker; arthritis for three years.	Began in both ankles, with pain, inflammation and high fever.	Ankles.	Ankles and phalanges.	Salicin for four days; then colchicin; joint special.	Salicin had no effect; patient developed temperature while taking it; yielded promptly to colchicin.
22	M.	28	Photographer.	Acute rheumatic arthritis	Negative.	Similar attack last summer.	Began with pain, redness and swelling in right ankle and foot; extended to left ankle and foot.	Ankles.	Both ankles; both feet; left knee.	Salicin; joint special.	At first patient had salicin (10 gr. every four hours) with no effect; was put on salicin (10 gr. every hour); promptly relieved of pain and swelling.
23	M.	35	Elevator man	Acute gouty arthritis.	Negative.	Drinks moderately; has had six or seven previous attacks in great toes.	Began with moderate pain in feet and toes, gradually grew worse.	Feet and great toes.	Great toe-joints, and both feet tophrase in ear.	Colchicin; joint special.	Yielded promptly to colchicin.
24	F.	40	Housewife.	Chronic septic arthritis.	Mother had rheumatism.	Has had several miscarriages; addicted to opium.	Following last miscarriage joints of knees and ankles became swollen and painful.	Knees.	Knees, hips and lumbar vertebræ.	Salicylates, and ichthyol baths.	No effect from salicylates, ichthyol bath gave relief, gradually overcame lameness and stiffness.
25	F.	48	Cigar maker.	Chronic gouty arthritis.	Negative.	Drinks heavily at times; had arthritis eight years ago with repeated attacks since.	Began with pain and swelling in knees, then to ankles, great toes and hands.	Knees.	Knees, ankles, great toes, and hands.	Colchicin; joint special.	Prompt relief with colchicin.
26	F.	42	Domestic.	Acute gonorrheal arthritis.	Negative.	Has had for some time profuse vaginal discharge.	Pain, swelling and redness came on suddenly in right wrist and hand; following day right foot became involved.	Right wrist and hand.	Right wrist, hand, and foot.	Bichloride of mercury douche; joint special; salicin.	Salicin had no effect; seemed to improve under bichloride douches.
27	F.	48	Cook.	Chronic gouty arthritis.	Negative.	Moderate beer drinker; has had several similar attacks.	Knee joints became swollen and painful; then went to thumb.	Both knees.	Both knees, metacarpophalangeal joint of thumb.	Salicin; colchicin; joint special.	Salicin for five days had no effect; prompt relief from colchicin.
28	F.	36	Housewife.	Arthritis deformans.	Mother had arthritis deformans.	Well until first attack ten years ago.	Began with inflammation and pain in feet; then with subsequent attacks all joints became involved.	Both feet.	All joints of both extremities.	Tonics.	

with the aid of crutches, and soon dropped the crutches for two canes. By early summer, about four months after he began his colchicum he left the hospital, having discarded his canes, and spent the summer in the country with friends. He was well enough to do light work, and in the autumn came back to the hospital to be cared for during the winter. His condition all winter was good, and there was very little soreness, which was always promptly controlled by increasing the colchicum. He left the hospital again on the advent of warm weather and has remained in very good condition since. Although colchicum has been taken continuously by this patient for over three years, except for short periods, it has never failed during this time to control all soreness and stiffness which might intervene.

The ichthyol bath is another measure which has been found very serviceable in these chronic cases. An ounce of ichthyol is put into a tub of water. The water is fixed at a temperature of 98° to 100° F., and the patient remains in the bath for ten to twelve minutes. The effect of the bath is the immediate relief of stiffness and soreness, which often lasts for forty-eight hours; the succeeding baths give longer periods of relief. It is a good plan to precede the massage and movements of the joints by such baths, as there will then be much more freedom of movement and less soreness on manipulation. In addition to the specific medication iron, arsenic, strychnine and other tonics were given as the occasion called for them. The diet was generous and nourishing, and only limited by the digestive condition of the patient.

Acute Rheumatic Arthritis.—These patients were put upon a milk diet, the joints done up in "joint special," as in acute gout, salicin in ten-grain doses was given every hour until the symptoms began to ameliorate, which usually took place within the first twenty-four hours. The salicin was then decreased, but continued until the patient was entirely free from fever and pain. Salicin is preferable to any of the other salicylic preparations, as it does not disturb the stomach or produce any unpleasant symptoms. To get the effect from it, however, it must be given freely.

The practice of putting these inflamed rheumatic joints in splints is much to be condemned. There is always more or less of inflammatory exudate thrown out about the joint in this condition, which becomes organized very quickly if the joint be rendered absolutely immobile by a fixed splint. A stiff joint which may take months to restore to usefulness is very often the sequence of such a procedure. With a soft dressing, such as described above, the joint is capable of slight movement such as would come from changing position in bed, etc., sufficient, however, to prevent the ligaments from becoming glued together, and as the soreness wears off, greater freedom of movement comes. In such cases passive movements can be instituted much earlier and the danger of permanent stiffness be very much lessened. It is exceedingly rare to find a case in which the pain is so severe with these slight movements as to render complete immobilization of the joint necessary.

In gonorrheal arthritis neither salicin nor colchicum has the slightest effect on the disease. In fact, so far as is known, there is no drug taken internally which will control the course of the affection. In the five cases in this series irrigation and local application to the urethra were used with very good effect. In two of the cases there were erosions of the urethra which were evidently the source of the affection. These were both etched with a 50 per cent. solution of nitrate of silver. One was cured after four etchings, the other was much relieved after each treatment, but was not entirely well at the end of the period. The one female in this group seemed to improve under bichloride of mercury douches.

For arthritis deformans which has reached the stage of the one case tabulated there is, of course, very little to be done. Good food and tonics are alone to be relied upon. The ichthyol bath will often give comfort, and static electricity does good in various ways.

Mention was made above of one doubtful case which might be either gout or rheumatism, where an intramuscular node in the trapezius was present. Such cases are not so very rare. Here there were present pain and stiffness of the muscle which were very much aggravated by movement. On examination the nodes were felt down deep in the muscle. The treatment consisted of massage and the administration of colchicin, under which the nodes in a very short time disappeared.

66 West Forty-ninth Street.

CONTRIBUTIONS TO THE PATHOLOGY AND TREATMENT OF ACUTE GONORRHEA.

BY LUDWIG WEISS, M.D.,

OF NEW YORK;

PHYSICIAN TO THE GERMAN POLIKLINIC, SKIN AND GENITO-URINARY DEPARTMENT; CONSULTING DERMATOLOGIST, HEBREW ORPHAN ASYLUM NEW YORK.

In all probability fully 90 per cent. of all urethral discharges are due to the gonococcus; the rest are caused either by pyogenic bacteria and the numerous unclassified microbal flora of the urethra or are due to chemical or traumatic conditions causing a catarrhal urethritis. These various conditions may be conveniently formulated under the following headings:

1. *Invasion of gonococci plus reactive emigration of leucocytes, pus serum and epithelial and eventually deeper structural lesions, i.e., gonorrhea, a specific and infectious urethritis.* Mircoscopically, we find mainly intracellular, intercellular and some extracellular gonococci, leucocytes, and epithelia; clinically, more or less inflammatory symptoms, usually copious discharge; complications and systemic metastases frequent.

2. *Bacillary, but non-gonorrheic urethritis.*—As a primary infection this form is very rare, and may be due to chemical or sexual influences; if present, however, it is of a quite chronic char-

acter, and often refractory to treatment. Casper[1] and Waelsch[2] have seen complications occurring with this form (prostratis). As a so-called secondary infection following gonorrhea, however, this form is very frequent and merits great attention. The healthy urethra is the habitat of a numerous innocuous microbial flora. While non-pathogenic for a healthy urethra, which they inhabit with impunity, these micro-organisms, when reinforced by the bacteria of pus or by bacillus *coli commune* may assume irritating properties in a urethra debilitated by the gonococcus or its toxins. The contributary causes for this kind of urethritis are: the ubiquitous pus bacteria, unclean instrumentation, chronic constipation, phosphaturia and oxaluria, the contamination with leucorrheal discharges, overtreatment, etc. Microscopical examination reveals micro-, staphylo-, and strepto-cocci, various diplococci, epithelia, leucocytes, mucus, Boettcher's crystals from the prostate or spermatozoa.

3. *Catarrhal urethritis, either simple primary or secondary aseptic urethritis, no pathogenic microbes.* The primary form is extremely rare. The secondary is due to a prolonged catarrhal condition of the mucosa, and occurs mostly as a terminal postgonorrheal discharge. Contributary causes: Sexual overindulgence, masturbation, sometimes even aseptic instrumentation, overtreatment, chronic prostatitis, bicycling, horseback riding, irritating drugs, urethral chancre, herpes, and a slightly mucopurulent discharge of recent syphilis caused by maculopapular lesions in the urethra. Microscopically, we find in this form mucus and epithelia imbedded in a network of fibrin; occasionally an accidental admixture of microbes as nosoparasites.

I will here consider gonorrhea only, due to the invasion of the gonococcus discovered by Neisser in 1879. It took some little time before this fact was accepted by the sceptical minds of medical men. Long before this gonorrhea had been attributed to a fungus called *Trichomonas vaginalis* by Donne,[3] to an alga called *genitalia* by Jusseaume,[4] to another fungus called *Conoiothecicum gonorrhoicum* by Hallier, and to spores called *Crypta gonorrhoica* by Salisbury.[5] It is only in historical justice to Salisbury that I here venture to credit him, for the first time, to my knowledge, with believing that he had really seen gonococci. He describes his spores as occurring in pairs and sometimes in fours, "undergoing the process of duplicative segmentation," developing rapidly in and among the parent cells of the urethral mucous membrane. "In some instances the pus cells become filled with the spores." He goes on further by stating—and here fate and lack of staining technic and of our high grade microscopes make him unwittingly deviate from a truth which it seems was within his grasp—that "the spores unite into filaments." In Eulenburg's "Real Encyclopedy," in the article "Gonorrhea," Gruenfeld, of endoscopic fame, in 1885, remarks incidentally that Neisser has found a micro-organism allegedly peculiar to gonorrhea, these being the only words attributed to a great discovery, already over six years old.

All this time, and well up in the 70's of the last century, the different urethral discharges were promiscuously called gonorrhea. The so-called strumous, herpetic, gouty, rheumatic, scorbutic habit was held to produce urethral discharges in conformity with ancient traditions not entirely eradicated in our times. We know that these constitutional anomalies do not cause urethral discharge, as was thought, but that they may prolong in such persons the duration of chronic gonorrheal discharge. Besides these diatheses there are innumerable causes for gonorrhea. Milton compiles 37, among which are hemorrhoids, dentition, ascarides, suppression of skin diseases, etc. There are some ludicrous causes of gonorrhea, like, urinating in the night air, against the north wind, the exertion of lopping a tree, a strain, cold from the closet, etc. *Omnis gonorrhoicus est mendax!*

But the main cause for discord was to decide the question whether leucorrhea, a catarrhal, non-specific inflammation of the vagina or uterus, could cause gonorrhea in man. Ricord[6] declared that gonorrhea is neither specific nor contagious, that it is due to different causes and may also be generated by leucorrhea. Diday, his genial pupil, asserts that any woman with a discharge may give gonorrhea. That all hapless husbands of such leucorrheal women did not acquire gonorrhea is due only to the most providential circumstance, that they are becoming acclimatized, so to say, to the special conditions of their wives. Gonorrhea may be given, says Linas,[7] by the most chaste of wives, while Fournier (Milton, *loc. cit.*) gives the ante to Ricord by maintaining that more frequently than otherwise a woman who gives gonorrhea may not have it herself. Bumstead[8] says that he has reason to believe that frequent repetition of the sexual act has produced gonorrhea in women free from any previous disease. These believers in the non-specific nature of gonorrhea are, however, grossly inconsistent in their reasoning when they maintain that if in a female the signs of infection are in the urethra, then specific gonorrhea is present, while when other parts of the genitalia are affected it is not gonorrhea. Even recently an authority like Lydston[9] holds that all inflammatory affections from the urogenital membrane are likely to be infectious, in spite of the absence of gonococci; it may develop *de novo* in the female sexual tract. The discovery of the gonococcus, he thinks to be only of relative clinical value.

As to the assertions of the first-named authors, I think the issues have been hopelessly confused. Microscopical and cultural experiments had not then revealed what is common property now, that is, the specific coccus, and its peculiarities and its inveteracy were unknown. As to the remarks of the last-named writer, they are entitled to the greatest consideration, coming from such an unimpeachable source. That gonorrhea must have

begun spontaneously somewhere and somehow cannot be disputed, and it possibly may again originate in the same way. But this reasoning may apply equally to diphtheria or typhoid; yet we do not maintain that any of these diseases originated *de novo*, but attribute their propagation from individual to individual. I am of the conviction that leucorrhea, simple or purulent, which does not contain gonococci cannot cause gonorrhea in the male; neither will intercourse with women so afflicted, either during or directly after the menstrual period, produce it. It may, however, cause a purulent, non-gonorrheic bacillary discharge of short duration and little irritation. I have never seen in such cases complications of the adnexa to occur. Where such complications have taken place it was due to latent gonorrhea, where under the stimulus of excitement reinfection occurred by dormant gonococci, which again became active.

In 1879 Neisser discovered the long-suspected parasite in the form of a peculiar diplococcus in urethral gonorrhea and ophthalmia neonatorum, calling it the "gonococcus."[10] It is readily distinguished by its coffee-bean form, dimensions, grouping in clusters of multiple fours, intracellular situation, and especially by its being readily decolorized by Gram's method, and by its somewhat difficult cultivation. The etiological importance of the gonococcus was undoubtedly established through the positive inoculations of Bumm[11] and of Wertheim,[12] which proved that a pure culture of the gonococcus implanted in a healthy urethra of man reproduced the disease clinically, microscopically and culturally, putting the specificity of the gonococcus as the cause of gonorrhea beyond a doubt. Soon a host of authors, especially Finger,[13] Steinschneider and Schaeffer,[14] and others, confirmed these results, while other investigators, like Young,[15] and of late Thalmann[16] facilitated the successful cultivation of the gonococcus so as to be almost within reach of any practitioner with some bacteriological knowledge.

Pure cultures of the gonococcus have been experimentally inoculated by many others since in several localities. Ahman[17] reports a case where a pure culture obtained on blood serum from a patient with gonorrheal arthritis was injected into the urethra of a man. In a few days a gonorrheal discharge developed and in turn a synovitis, which showed gonococci present in pure culture. Finger and Bockart[18] in 1883 made urethral inoculations with successful results. Hansteen[19] obtained pure culture of gonococci from operated cases of inguinal adenitis, inoculating it in the urethra of a healthy man and causing real gonorrhea. Successful cultivations from cases of arthritis, subcutaneous abscess, acute and chronic cystitis, pyonephrosis and peritonitis were obtained by Young[20] and others. Lang and Paltauf[21] report such abscesses on the dorsum of the hand. In a patient with gonorrhea referred to me by Dr. M. Goldberg, of this city, I have seen a severe exudative inflammation of the right wrist. Examination revealed gonococci. Similar cases are reported by Horwitz,[22] Bujivid,[23] and Jundell.[24] I have seen a case of painful swelling of the costosternal cartilage in a patient aged forty years, who had gonorrhea.

To mention just a few other instances of systemic gonorrhea I will quote a case of gangrene of the foot and leg by embolism of the femoral artery through ulcerous endocarditis caused by gonorrhea,[25] rupture of the aortic valve in consequence of a verrucous mass containing gonococci.[26] Also a similar case by Keller,[27] but situated on the valves of the pulmonary artery following gonorrhea. Alfred Stengel,[28] also Bales and Siaen,[29] J. Adler,[30] and others, report cases of fatal blennorrhagic endocarditis and pyosepticemia. Wertheim[31] reports a case of gonorrheal cystitis with thrombophlebitis of the bladder. While even Finger, Bumm, Sänger and Guyon, regard the latter complication as caused by a mixed infection, it was shown by Melchior,[32] Wertheim, Lindholm[33] and others that gonococci alone were found in the mucosa of the bladder, in the venous capillaries, and in the urine of these patients. Colombini[35] and others found albuminuria due to general blemorrhoic infection. Roswell Park[34] reported several cases of gonorrheal pyemia. Salpingitis as a contiguous infection occurs in from 23 to 70 per cent. of all gonorrheas in women.

We are most conversant with the painful affections of the joints, well-known as gonorrheal rheumatism, of inflammations of the synovia of the joint, and of the sheaths of the tendons, as tendosynovitis. These latter processes have been recently observed even in children. Smith[36] found an infant, fourteen days old, with ophthalmia neonatorum afflicted with gonitis dextra. Griffith[37] observed iritis to be a more frequent complication of gonorrhea than of syphilis. Acker[38] reports a case of multiple arthritis in a girl, two years old, afflicted with gonorrheal vulvovaginitis. Lazarus,[39] in quoting Engel-Reimers' case of paralysis of the larynx, describes a case of posticus paralysis necessitating tracheotomy in a patient with gonorrhoic arthritis.

The influence of the gonococci upon the nervous system has been already observed by Charcot[40] in 1887, Leyden[41] 1892 as gonorrhoic polyneuritis especially of the lower extremities. Sellenew[42] coincides with Christmas[43] that the gonococci and the gonotoxins form a most energetic poison for the nervous system. They may cause alterations in the sensitive, vasomotor, secretory, trophic, and motor nerves, and also of the skin and tendon reflexes. Orlipski[44] describes gonorrheal neuroses; Kienbock[45] and Ware[46] report blennorrhoic neuritis and myositis; Glyn[47] and Kankarovitsch,[48] besides multiple neuritis, describe paralysis as a complication of gonorrhea, and Welander[49] observed a fatal case of polyneuritis due to gonorrhea.

The osseous system has been also reported as affected by Philippet,[50] who mentions gonorrheal osteitis and periostitis, especially of the small bones of the hand and foot, and Kieubock,[51] who demonstrated by radiography atrophy of the

wrist, elbow and hip joints. I have observed in a physician arthritis of the fibrous parts of the vertebral column, with excessive pains and stiffness as a post-gonorrhoic affection.

Finally skin affections, like erythema nodosum, hyperkeratosis and urticaria[52] have been observed as sequelæ of the ubiquitousness of the gonococcus or its toxins, and pyemia, iritis, pleuritis, etc., acute general peritonitis[53] by Wertheim,[54] Walton,[55] Cushing,[56] and others; all these manifestations showing general systemic infection by extensions and generalizations of the gonorrheic process. A veritable mine of information on systemic (metastatic) gonorrhea can be found in the work of Schneider,[57] and v. Hoffman,[58] which contain a compilation of all published cases since 1880. Sturgis[59] also deals ably with this question.

But well known as these facts are, it has puzzled us not to find the gonococcus in some of these metastases, although they were in casual connection with the gonorrheal process. Wassermann[60] and Scholtz[61] have shown that gonococci produce toxins, that is, products of their metabolism. It may be inferred that these toxins are the cause of such metastatic processes, where painstaking cover glass and culture examinations do not reveal the presence of gonococci. The toxins in such a case might have been set free by the dissolution of the germs, but in most cases the presence of the gonococci was demonstrated.

PECULIARITIES OF THE GONOCOCCI.

These local and general manifestations of gonorrhea have their analogue in other microbial infectious diseases. We have all seen cases of diphtheria, or of streptococcus infection or lacunar mixed infection of the tonsils remain local, causing no systemic disturbance, while in some instances the most foudroyant general infection takes place. We try to explain this by the assumption that in these cases the Klebs-Löffler bacillus or the streptococcus did not generate toxins or that its toxins were neutralized in one instance and not so in the other. Even as to the dreaded persistency of the gonococcus we find similar conditions in other microbial diseases. I have seen the bacillus of diphtheria demonstrated by cultivation from the tonsils of patients who had the disease five months before. We know that the bacillus of Eberth, the typhoid bacillus, has been found in the urine and spleen six months after infection. They, as well as the gonococcus, after such protracted reproduction upon the same soil, lose their virulency almost to the point of innocuousness, but they become virulent again when transported to a new soil. But it is questionable as yet whether in those cases a reinfection can take place in the same individual, as is the case with the gonococcus under the influence of an irritating cause.

Here it seems the analogy ends; probably because gonococcus life has been studied more closely. We know that the gonococcus may lie dormant in Littre's glands, or in the secure depths of Morgagni's crypts, in Cowper's, in the ducts of the prostatic glands, or in the remote abodes of the seminal vesicles. The "morning drop" of the patient may not show the presence of any gonococci, the scrapings of the urethral mucosa, the careful and trying examination of the threads in the urine may all prove negative, and yet there may be gonococci hidden in the contiguous tissues and glands. There they lie, seemingly innocuous in their latency, until a sudden mechanical impulse sets them free. Excesses *in Baccho et venere* and irritations of the genitalia of a kind to cause often-repeated hyperemia; overindulgence, better known as the much complained-of "strain"; chronic prostatitis, perchance even constipation, all these may cause, in a mechanical way, an expression of gonococci and a new invasion of the urethral mucosa by them.

The reported cases of acute diffuse gonococcus peritonitis (*loc. cit.*) developing during menstruation and following a recent exposure to infection, will recall to the mind of the practitioner such cases of peritonitis in the puerperal state where, in spite of the most minute asepsis and an uneventful delivery, septic peritonitis has set in. Likewise cases of parametritis and perimetritis, will be remembered that have started with the onset of menstruation and have been attributed to taking cold, to a strain, and to other such unproven incidents. There has always been, and there is yet, a suspicion in critical minds concerning the origin of these exudative pelvic inflammations. In the light of the ubiquitousness of the gonococcus, and the obscure and circuitous ways of its acquisition, it is perhaps not too hazardous to maintain that a goodly part of ascending pelvic inflammations, unrecognized as to their etiology, are due to gonococcal infection, either by the coccus itself, or by its toxins. The puerperal and menstrual states, with their attendant congestive conditions, might create an especially receptive medium for the propagation and invasion of dormant, or, as the case may be, of a recent and active brood of gonococci.

Furthermore, the life history of the gonococcus is of such a retributive character that it stops short of nothing. A man affected with chronic gonorrhea of a form so slight that he may be unconscious of its presence, may become refractory to his own gonococci. But transplanted to a new soil they will become virulent in the vaginal mucosa of their new host. By this implantation on a new culture medium, the gonococci may again assume a degree of virulency which, in turn, is capable of infecting the man who bore the ancestors of such gonococci with immunity. By some as yet unknown biological transformation they become alien to the soil they have before inhabited with impunity to its bearer. It is evident, therefore, that a woman with an exudative parametritis or perimetritis, acquired from latent gonorrhea of a man, may be able, after sexual relations have been resumed, to infect that man with just as virulent a type of gonorrhea as if acquired by any impure illegitimate life. The physician who is well acquainted with all these

possibilities of gonococcus life, will be able to explain and to redeem a seemingly lost reputation.

STERILITY.

The main cause of sterility in both sexes we know to be gonorrhea. While syphilis provokes miscarriage it does not hinder propagation in the male and conception in the female. A reasonably energetic and well-conducted antisyphilitic treatment will, as we know, attenuate the virus, or even annihilate it, so as to make both factors capable of procreation; else would it be a questionable blessing to propagate inferior individuals. Syphilis, although tainting it, does not destroy the vitality of the semen, but impairs gestation by weakening the retaining power of the womb. This is a wise defensive step of Nature to eliminate those which would otherwise be born with misery to themselves and others. Gonorrhea, however, destroys not only fecundation through azoospermia and nekrospermia in man (indurative epididymitis) but gives through the persistency of the gonococcus in the prostate and seminal vesicles an infectious character to the otherwise healthy semen. Latent gonorrhea with dormant gonococci in the prostate, seminal vesicles, Cowper's glands, or in the deeper glandular structures of the urethra, also strictures, indurative urethritis, cavernitis and resulting malformations; in the female endometritis, metritis, salpingitis, ovaritis, as pointed out by Bernultz[63] in 1857, and most emphatically by Noeggerath in 1872,[64] will add their destructive mites to the impaired virility in men and conception in women.

Gonorrhea, therefore, which is acquired by probably 80 per cent. of men is to be looked upon as a disease of the masses and as the main cause of depopulation; depopulation resulting through a decreased birthrate and the morbidity in women so affected who are either maimed by necessary surgical interference or succumb to the later manifestations of gonorrhea. Neisser's assertion that it is more frequent than measles is a comparison lucidly conveying to the mind its frequency at a glance. Gonorrhea does not only affect the working and earning capacity, but also the health of the people. Eighty per cent. of all deaths from pelvic disease in women are due to gonorrhea. Twenty per cent. of all blindness is due to gonorrheal infection of the newborn. Fifty per cent. of all involuntary childless marriages are caused by gonorrhea of the female organs of generation, of which 45 per cent. are due to marital infection by men. Race suicide, therefore, after all, is less a question of marital precaution than of matrimonial incapability.

This cursory allusion to the social danger of gonorrhea is sufficient cause for advising individual prophylaxis that has proved both promising and feasible.

General Prophylaxis.—To combat an affection so widespread as gonorrhea, which merits the attribute of a pandemic, exercising its deleterious consequences for ages, although the knowledge of their real importance is of comparatively recent date, must have stimulated mankind to preventive measures. It lies not in the scope of this paper to deal with the moral aspect of the question; the writer has done so extensively in an article read before the Fifty-third Annual Meeting of the American Medical Association, at Saratoga, in 1892[64] to which I beg to refer the reader. I would only briefly remark here that it is not for the sake of the profligate that we recommend prophylactic measures, but to save the innocents who are threatened with a tedious, devitalizing, and destructive disease, tainting the yet unborn, and maiming and invalidating those living. It is evident that continental measures against prostitution have proved futile wherever tried; they sterilize only a small number of foci and invariably augment clandestine prostitution. While in this country, besides sentimental reasons, constitutional rights, moral considerations, etc., are inimical to the adoption of such means. I declare most emphatically, however, that the State cannot with impunity fail to take cognizance of the plague, and that between the unwholesome conflict of sanitary and moral interests I have found that morality is in no way increasing by relegating the sanitary aspect of the question to the background. Some State legislation, not necessarily reglementation, is needed. Moralists and sanitarians must make mutual concessions on a common platform. Until such combined efforts will meet their realization, we must, under the present conditions of moral evolution of the race, take hold of the nearest measure available, and this is *special individual prophylaxis.* People ought to be enlightened on sexual hygiene and the innocuousness of continence. The dangers of gonorrhea—too frequently underestimated, or even frowned upon as yet—and the manifold ways of communicating it, should be explained to them.

Among venereal diseases gonorrhea is the only one in which the causative factor, the gonococcus, is known; consequently agents for the destruction of the pathogenic germ *before* incubation has set in, have been devised with success. It consists (analogue to the Credé instillation in ophthalmoblennorrhea) of the instillation, immediately or shortly after exposure of a two per cent. solution of silver nitrate or of the more recent silver preparations. Prophylactic measures which prostitutes are compelled to use under Continental reglementation are under the reigning circumstances here out of the question.

The *treatment* of gonorrhea may be summarized as follows: (1) Treatment by prophylaxis; (2) the abortive treatment; (3) the expectant treatment without remedies; (4) treatment with remedial agents combined; antiphlogosis; (5) active etiological treatment followed by treatment of lesions.

1. The *treatment by prophylaxis* is coincident with the prophylactic measures mentioned before.

2. *The Abortive Treatment.*—In ancient, in medieval, and in the present times, and before the

microbial conception of gonorrhea, innumerable attempts to eradicate the process in its incipiency were made. But the abortive treatment was elevated to the dignity of a method through Ricord[65] and his followers (Diday, etc.) in 1851. It consisted of the injection into the urethra of a strong solution of nitrate of silver, 10 to 15 grains to the ounce, after urinating. The result was gratifying only in a minority of cases. In the others phlegmonous inflammations, suppression of urine, suppurative prostatitis, and other serious complications supervened. Welander,[66] in gonorrhea of not more than three days' standing, destroyed the epithelium of the meatus and fossa navicularis until capillary oozing ensued, and then injected a 2 per cent. solution of nitrate of silver for two minutes, following it with injections of salt water. Hugues[67] used the same procedure, injecting bichloride in the strength of 1 : 1,000. Koester and Jadassohn, 1892,[68] recommended ichthyol, and Janet[69] in 1892 published his abortive method of large flushings with strong solutions of permanganate of potassium 1 : 2,000 to 1,000, which he soon changed (1894) into his well-known modified abortive treatment by irrigations of the same drug in the strength of from 1 : 4,000 to 1,000. Neisser, after the gonocidal power of silver nitrate had been established at his clinic by Friedheim in 1892, injects a solution of it in the strength of 1 : 3,000 to 1,000. Feleki[70] cauterized the urethra with a solution of nitrate of silver 1 to 20 through the endoscope. He effected a cure in all his twelve cases in from four to twenty-one days: a rather too optimistic result when we consider that five of his cases were first infections and several had several infections. Kopp[71] reports 25 per cent. of cures in cases that presented themselves fourteen hours after exposure. In most of these cases a profuse, bloody, purulent discharge took place, with violent pains and inflammatory symptoms. Statistics to this effect, although given by honest conviction, are not always reliable.

With the introduction of the new silver salts as eminently gonocidal and non-irritating remedies, the abortive treatment of gonorrhea has assumed a new aspect. If by the use of these remedies we should happen to fail in our attempt we have at least not done any harm, as was the case, I believe, with nitrate of silver. Welander,[72] in 1898, and afterward Ahlstrom, in 1900, were the first to use these preparations as an abortivum, employing protargol in a 3 to 4 per cent. solution, thrice daily, for three days, with about 50 and 83 per cent. respectively of positive results. They maintain that if used within a few hours after infection it will act as a positive abortivum. Blaschko,[73] in 1902, is also a zealous adherer of the abortive cure of gonorrhea. He has given up a 2 per cent. solution of nitrate of silver for this purpose, and uses instead injections for three days of a 1 to 2 per cent. solution of albargin, or a 4 per cent. protargol solution, retained three to five minutes. He reports absolute absence of all irritation, and a positive result in 50 per cent. of the cases. He considers the ease of application as a great advantage over the Janet method. Frank is of the same opinion. Bierhoff,[74] in a paper read before the German Medical Society, December 7, 1903, reports a series of thirty cases treated abortively by injections of protargol. He used it in cases where the second portion of urine was clear, showing no posterior involvement. In fifteen cases of first attacks he had negative results, while in the other fifteen, who had two or more attacks, the results were positive. In the first series of cases, however, the patients did not present themselves earlier than the sixth day after infection. Other writers, like Christian,[75] maintain that gonorrhea cannot be aborted.

To me it is not so much the question of the remedy used as the question of principle which needs to be decided, Can we abort gonorrhea? Between the unfruitful conflict of the pros and cons, the weight of evidence is in favor of the former. There certainly must be a time-space—it varies from eighteen hours to three days—within which the gonococci, despite their quick penetration, are superficial and capable of being killed. Granting this, their early destruction is a possible proposition. But the prodromata of gonorrhea are, unfortunately, of such latent, hardly perceptible nature that only the hypochondriac self-observer, or one especially interested in the hygiene of sexual life—rara aves—will apply the remedies in the period of incubation. Therefore, I would call aborted only such cases which are so treated within thirty-six hours after infection as the utmost average limit. I would recommend such a procedure when the microscope shows abundant gonococci on epithelial cells and only very few leucocytes. Cases that are successfully cured forty-eight hours or more after infection I look upon as having yielded to immediate early treatment, or prophylaxis by treatment in the ordinary sense of the word.

3. *Expectant Treatment Without Remedies.*—It has been maintained by those favoring conservatism that gonorrhea is a systematic infectious disease with rise of temperature, increase of leucocytes, enlargement of the lymphatic glands and spleen, and having its stage of incubation, flourishing and defervescence. The theory propounded by Sternberg, in 1881, and elaborated by Metchnikoff, in 1884, of phagocytic action of leucocytes, to engulf and destroy micro-organisms, has been generally accepted. But it seems to me too phantastic to deduce from it the absolute nihilism as to treatment by further maintaining that the infective agent must not be destroyed, as it generates substances—antitoxins—or so-called defensive proteids, which must be looked upon as Nature's remedial agents. We have reason to believe that gonorrhea will heal spontaneously. But in treating, for instance, a case of typhoid or pneumonia on the expectant plan, we do not indulge in absolute nihilism either. The patient is in bed; his hygiene and dietetics are looked after. Our social conditions will permit only a very limited number of gonorrhoics to take to their bed. The exi-

gencies and exertions of business life will frustrate a spontaneous cure. With their unchecked discharge they are menace to others and to themselves. It is therefore obvious that, as in the present state of our knowledge, we cannot depend solely upon the curative action of Nature's endeavors; if judicious antiparasitic treatment is instituted to support these, the chances of recovery and the avoidance of complications are in favor of the patient.

4. *The Expectant Treatment with Remedial Agents (Balsamics) Combined.*—I have certainly seen patients who had refused other kind of treatment get well under the sole use of balsamics, of course, so far as stopping of the discharge and the discontinuing of attendance may be taken as a sign of a cure. It is held by some that the balsamics should not be administered in the acute stage, as they stimulate the urethral mucosa at a time when all irritation should be avoided. This point is not well taken. May I ask of those who irrigate in the most acute stages, whether the pressure irrigation of the urethra from outward within is less irritating than a flushing of the urethra with urine impregnated with the infinitely less irritating products of the balsamics, through the natural channels from within outward. Finger administers the balsamics in those cases where acute symptoms supervene and injections would only increase the distress and also in the usual run of cases when injections are at once applied, thus combining both agents. On the contrary, Taylor[76] and Pedersen[77] employ the balsamics only when the inflammation begins to decline. Most German writers use them from the beginning.

Considering the pathology of gonorrhea that the discharge is the repelling act of the organism to flush out the gonococci, and considering that the balsamics tend to stop the discharge at a time when increased leucocytosis is essential, I do not for this reason recommend the exhibition of the balsamics before the acme of inflammation has declined. I also, however, regard them as an adjuvant of great value beyond this stage.

As to their mode of action, theories differ. The experiments of Ricord and of later writers tend to show that the urine impregnated with the disintegrated or liberated products of copaiba balsam or santal oil—most probably resinous acid and ethereal oil—and united according to Weikart with the alkalies of the circulation as sodium copaibate or sodium santalate, acts as a local detergent to the urethral mucosa, making it (laboratory experiments to the contrary) a less productive culture medium. Among the long list of balsamics, santal oil is justly the most employed by virtue of its lack of disagreeable properties and positive effectiveness. It sometimes produces congestion and pain in the kidneys, and should then be stopped at once. It is best given in capsules containing 10 drops, three times a day.

As to the antiphlogistic treatment the antiquated way of leeching, etc., has only an historical interest; but even in our pro modern times a certain amount of rest, cold applications, spare diet, regular evacuation, and the copious drinking of water, demulcents, and alkalies or an infusion of folia uva ursi, are very recommendable, but by no means obsolete adjuncts. I have found prunes a pleasant means of rendering the urine alkaline.

5. *Active Etiological Treatment, Followed by Treatment of Lesions.*—This can be done, first, by the Janet method of copious irrigations with permanganate of potash, and second, by injections of the new silver salts by hand syringe. What is called the modern treatment of gonorrhea, a term so often used of late, comprises the endeavor to treat gonorrhea according to its etiology. The excitant factor being the gonococcus of Neisser, its removal and eradication should form the main and primary object of our action. If the etiological treatment of acute gonorrhea with the silver proteid preparations would be instituted as speedily as possible it would diminish complications of the glands and lacunae of the anterior urethra, acute and subacute posterior urethritis, cowperitis and prostatitis, and incidentally chronic urethritis and prostatitis. While acute posterior urethritis, which is regarded as the most usual complication, will develop in 70 to 80 per cent. of cases treated in the beginning with astringents, we will find it when employing the new silver salts only in 30 per cent., and according to some statistics in only 10 per cent. of cases.

(To be Continued.)

RECENT ADVANCES IN THE THERAPEUTICS OF PEDIATRICS.

BY NOBLE P. BARNES, M.D.,
OF WASHINGTON, D. C.

The most eloquent argument that can be advanced in proof of the worthiness of this branch of the art, is the remarkable reduction in infant mortality in all civilization. Our large cities[1] point with satisfaction to the decline in the death rate of children in the last ten years, and further improvement may be confidently expected with a more thorough application of recognized knowledge.

In this contest of human existence, much depends upon getting a good start, and some of these infants that are being saved have a hard struggle shaking off the iniquities of their fathers. It is an established fact that the children of young parents are stronger and of better health than those of parents who marry late in life. It is to be expected that the child of a gouty, nervous club-man and a broken-down society belle will inherit the tissue proclivities and endowments incident to a life of more or less dissipation.

Several conditions are eminent: (1) belated marriages result in diminished birth rate; (2) the increase of cancer is only among the nations in which the marriage age has been steadily advancing; and (3) the psychosis noticeable in a large percentage of children depends, not so much

upon school life, as upon inheritance and the nutritive process of the developmental period.

The medical inspection of schools has only begun to accomplish what is within its possibilities, and the future school will have its medical attendant who will not only exclude children suffering with contagious diseases and those who have other diseases rendering them too ill to remain in school, but will direct those mentally and physically defective and determine the amount of school work a child is able to perform.

Most college teachers recognize the fact that when normal students eat, sleep and exercise wisely there is little danger from over-work, and their college stay is attended with health improvement. It should be more generally known that every scholar is not intended by nature to be a professional man. Many a good proletarian has been led astray by being encouraged to believe that "any one with a sufficient stock of impudence may reasonably well pass for a physician."

Experimental and clinical observations have served to emphasize many well-known facts respecting infant feeding. The danger from raw milk in the summer is conclusively demonstrated,[2] and universal pasteurization is a most important factor in reducing infant morbidity and mortality.

Behring[3] and Richie[4] argue in favor of using preservatives, and place especial stress upon formalin in from 1 to 500 to 1 to 10,000. Behring claims that formalin in these proportions is tasteless and harmless; that the curdling is more flocculent, the milk more digestible and the immune and antibodies unimpaired. Personally I have had considerable annoyance with milk containing formalin, making it impossible to put the milk through the first process of digestion. If, then, this formalinized milk resists the action of pepsin, the enzymes of the milk must also be destroyed, and its digestibility must be greatly impaired.

The recommending of preservatives for milk is an exceedingly dangerous procedure, and its enactment would encourage careless and indifferent dairymen to deliver any amount of filth. Electrical preservation, now under experimentation, may clear this problem for the future. Just now we are most concerned in the production of a pure, clean milk and its adaptability by suitable modification to individual cases.

The selection and care of the milch cow, the handling of the milk, and its modification for the infant has been thoroughly presented to the profession, and I will take time simply to mention that the outline suggested by the United States Department of Agriculture for the improvement of market milk should be inforced by law.

Buttermilk feeding[5] has been revived, and its advocate believes it to be a life-saving preparation for sick children. Men frequently lose sight of the modification of sweet whey, which is the sheet anchor in digestive disorders. Usually when a physician vibrates from boiled flour and buttermilk to proprietary foods and condensed milk, he demonstrates to everybody, possibly himself included, that as a baby feeder he is a failure.

The exact rôle of the Shiga-Flexner bacillus in summer diarrhea is still under consideration. The organism was found in 62 out of 64 consecutive cases examined at the Vanderbilt Clinic.[6] These cases presented all the clinical types, from the mildest intestinal indigestion to severe colitis. Twenty per cent. of them were breast-fed, and of the fatal cases a large number showed no evidence of profound structural lesion.

Flexner and other workers in this field believe that the bacillus of dysentery produces the primary lesions early, and the subsequent pathological change is the result of a mixed infection. This being the case, the antidysentery serum of Flexner, in order to be of much virtue, should be given early and before the usual mixed infection and anatomical changes occur. Holt[7] reports use of the serum in eight cases, two of which were moribund. In three no effect was seen, and in the other three improvement was strikingly apparent.

Zahorsky[8] concludes the report of his experience with the statement that monovalent antidysentery serum is too uncertain for general use, but the polyvalent serum should be given in all cases of summer diarrhea.

Hastings[9] concludes his report of the *Bacillus dysenteriæ* in Boston and vicinity with the statement that no "positive conclusions can be drawn from our experience with the serum." "We are confident that no harm was done." The judicious employment of gelatin[10] and olive oil[11] makes an important addition to the well-recognized management of ileocolitis.

The serum treatment of typhoid fever has received considerable encouragement from Josias,[12] who reports fifty cases with a mortality of 4 per cent., while during the same period other cases treated in the usual manner gave a mortality of 14.2 per cent. When injected at the onset, the dose given was one cubic centimeter to every thirty kilograms of weight. In one-third of the cases the temperature descended on the day of injection and continued to fall until convalescence. Patients inoculated before the seventh day made a quick recovery. In a few the treatment seemed to have no influence whatever, and in young children the injection was sometimes followed by severe abdominal pain that continued for several days, giving suspicion of peritonitis.

Einhorn[13] recommends early injection, even before diagnosis is certain. In his cases the treatment was instituted from the ninth to the fifteenth day. He notes the reduction of temperature from one to two degrees and the general improvement of the sensory and nervous symptoms. De Rochemont[14] reports his experience with Jezz's serum, and concludes that while wonderful cures can not be cited, in every case the course was modified and rendered milder, though not shortened.

Pertussis has received its annual allotment of therapeutic agents, all of them of inestimable value in the hands of the originator. Arnheim makes the remarkable statement that the "paroxysms are to be considered a healing process by

mechanically removing the specific bacteria." Most authorities agree, however, that the paroxysm is the most distressing and the most dangerous part of the disease, and treatment directed to its relief is rational.

Formaldehyde[15] in from one-half to one per cent. solution, sprayed into the pharynx once a day; two per cent. solution of flouroform,[16] given in doses of from 100 to 150 grams daily; and calcium sulphide[17] in .03 gram doses every hour or two until the breath smells of hydrogen sulphide; are among the remedies receiving much support.

Manipulation of the lower jaw after the method of Naegeli,[18] will control the paroxysm in most instances in older children. Mothers and attendants should be instructed in this procedure. The control of the laryngismus relieves the usual vomiting and resulting emaciation, and with the supportive measures, good food and fresh air, meets the indications.

The fresh air treatment[19] is emphasized in the records of the Edinburgh Hospital. Of 74 cases treated indoors 51 died, a mortality of 66.9 per cent. Of 76 cases treated out of doors, partly or entirely, 24 died, a mortality of 31.5 per cent.

Dr. Mallory's[20] finding a series of bodies in the skin and superficial lymph spaces of four patients who died in the eruptive stage of scarlet fever, is far from proving the etiological factor of this disease. Dochle,[21] twelve years ago, described a peculiar variety of protozoa which he found in the blood of patients suffering from some of the eruptive diseases, among them scarlet fever. His findings were never confirmed.

We do know, however, that the streptococcus is present on the tonsils in almost every case; in the blood in 15 per cent. of the cases during life, and in 80 per cent. after death.[22] It has not been found in the blood before the third day. In fulminating cases the organism may not be demonstrable, but when uncomplicated with streptococcemia, scarlet fever usually runs a mild course. The streptococcus is generally accountable for the severity of the disease, especially the complications and sequelæ, and these complications can be prevented by the early use of an efficient serum administered in sufficiently large doses.

From the literature of the past twelve months I have collected 384 reported cases, and about double that number mentioned where the antistreptococcus serum has been administered in this disease. The largest number reported by any one observer was 112 cases treated at St. Anna Kinderspital by T. Escherich.[23]

In order to test the merits of the serum, Escherich employed it only in severe cases in which the toxic symptoms predominated. In doses of from 100 to 200 c.cm. early injected, he claims the serum acted almost like magic. In from four to twelve hours the temperature fell, the pulse and respiration slowed and the exanthema faded. The temperature remained normal in favorable cases, and the eruption disappeared on the following day. In less favorable cases there was some slight rise in the temperature of short duration. In later cases with necrotic pharnyx, glandular enlargement and other complications, the injection was without value. The mortality was reduced one-half. The summary of his cases is as follows:

Of 38 cases injected on the first and second day all recovered; of 27 cases injected on the third day two died, mortality 7.4 per cent.; of 23 cases injected on the fourth day four died, mortality 17.4 per cent.; of 20 cases injected on the fifth day six died, mortality 30 per cent.; of four cases injected on the ninth day two died, mortality 50 per cent.

Escherich believes the day not far distant when antistreptococcus serum will stand in the same relation to scarlet fever that antidiphtheritic serum does to diphtheria.

The summary of the changes noted by the various clinicians can be stated briefly as follows: Fall in temperature, decrease in the frequency of the pulse and respiration, and an improvement in the tension and rhythm of the former, clearing of the sensorium, prevention or amelioration of complications and rapid convalescence.

A polyvalent serum, containing the antibodies of human streptococci, is the only one to be depended upon. The serum appears not to destroy but to reduce the virulence of the organism, thus enabling the tissue cells to become more energetic in defense, indirectly favoring phagocytosis and absorption.[24]

Early use of the serum is to be recommended in all cases of scarlet fever, and in all other diseases where the streptococcus is playing a primary or secondary rôle. Smith[25] reports use of the serum in a series of smallpox cases with excellent results.

Widowitz[26] reports the use of urotropin in 102 cases of scarlet fever without a single case of nephritis. He gives from .05 to .5 grams, according to the age, during the first three days of the disease, and again at the beginning of the third week for another three days.

Seiffert[27] has had some remarkable results from the employment of lumbar puncture in uremia occurring in scarletinal nephritis. In several cases he withdrew from five to thirty cubic centimeters of spinal fluid. Cases with loss of consciousness and stertorous breathing recovered consciousness in thirty minutes after the operation and subsequently recovered entirely.

The therapeutic suggestions and clinical observations of chorea minor have been about as important and conclusive as the pathological[28] and bacteriological findings.

We are constantly confronted with individual predispositions in children, born of neurotic stock, that are influenced by the slightest degree of nerve pressure, whether it be of school, adolescence or reflexes; and an infection or intoxication that would pass unnoticed in well-balanced nervous systems, would in these produce chorea or many other nervous phenomena.

The association of chorea and "rheumatism"

can be demonstrated in the majority of cases if kept under observation sufficiently long. The rheumatic complication of the first attack is frequently overlooked, because the heart is not carefully examined, the fever of a low degree is unobserved, the "growing pains," enlarged tonsils and case history is not considered. Microorganisms of the streptococcal group have been found in both of these disorders,[29] and may possibly have had something to do with the individual cases examined, but we have no proof of their constancy or their specific character. The report of a single case[30] that resisted all treatment until fifteen injections of antistreptococcus serum was given, only proves that this particular case was either due to or complicated with the streptococcus, that the serum used must have been of low potency, and that it would be well to examine the blood of all these cases and use a serum when indicated.

Inasmuch as we find chorea complicating pronounced anemia and infectious diseases, not associated with rheumatism, we are led to believe that many organisms and ptomains are capable of producing these same muscular spasms. Where there is any indication of "rheumatism" in these cases, treatment should be begun with sodium salicylate from .2 to 1 gram dissolved in a glass of water and taken two hours after meals.

The colossal doses and method of administration recommended by Lees[31] would put any stomach out of commission before it is time to take up the arsenic treatment. Smith[32] uses 4 c.c. doses of the fluid extract of ergot every three or four hours, in children of seven years, and continues the treatment for weeks if necessary. In stubborn cases he increases the dose to 6 c.c. and adds a moderate dose of strychnine. He regards this treatment as more reliable than the arsenic treatment, but the report of only two cases does not justify the conclusion.

In the management of pulmonary disorders there is nothing so important as fresh air, sunshine and isolation. As 50 per cent. of the pneumoniæ are due to bad air, more than half of these secondary inflammations should be avoided.

Many of these cases do well on the cold air treatment,[33] but infants and young children must have their air at 68° F. to prevent the irritating cough. The early respiratory disturbances, with dryness and congestion, are benefited by inhalations[34] of steam carrying eucalyptus, creosote, tinct. benzoin comp. and aromatics. If these inhalations are given under a tent and there is a lack of fresh air, oxygen may be administered simultaneously.

These cases must be supported, but not overfed, by a suitable amount of easily digested or predigested food, with an abundance of water. As long as the fever is doing no damage and the child is comfortable, it should be let alone. Cold applications can usually be limited to the head. The tepid sponge bath and hot mustard foot bath are excellent measures for equalizing the circulation.

The use of poultices, packs and jackets is dying out with the good old grandmother. Mild stimulating applications, as that suggested by Acker of equal parts of the oils of olive, amber and clove, are more pleasant and efficacious, and have none of the objectionable features.

The potassium iodide treatment of pneumonia is lauded by Altschul,[35] who claims not to have had a death in twelve years, out of 62 cases. His method is to give an initial dose of 10 or 15 grains, increasing it by 5 to 10 grains, every two or three hours day and night, according to the severity of the case, until defervescence is well established. In this manner he has given from 1,000 to 3,000 grains of the drug daily in a 50 per cent. solution in milk. One patient, a child, received over half of a pound of the drug in two days (2,100 grains daily for two days) without showing any signs of intolerance.

In cerebrospinal meningitis lumbar puncture, withdrawal of fluid by aspiration, and injection of 3 to 12 c.c. of a 1 per cent. solution of lysol, after the method of Seager,[36] omitting the canal washing with normal salt solution, has proved of great virtue in three cases reported by Manger,[37] and is considered a hopeful measure by Franca.[37]

Fat in Pigments.—By employing specific stains for fatty tissue, E. Sehrt (*Virchow's Archiv*, Vol. 177, No. 2) could detect the presence of fat in all pigments, even in those causing brown atrophy of the heart and liver. Lutein of the ovary is the only pigment in the human body which may be classed among the liprochroms, since it gives the sulphuric acid and the iodine reaction. Even after tissues have been subjected to fat-solvents for a long time, the sudden reaction will still be positive, which is not the case with the other pigments.

HEREDITARY CHOREA IN EIGHTEEN MEMBERS OF A FAMILY, WITH A REPORT OF THREE CASES.

OF MONTREAL, CANADA;
CLINICAL ASSISTANT IN NEUROLOGY, ROYAL VICTORIA HOSPITAL; ASSISTANT DEMONSTRATOR IN PATHOLOGY, MCGILL UNIVERSITY, MONTREAL.

Many cases of hereditary chorea have been reported since Huntingdon, in a few happy sentences, described the symptoms, but it is somewhat unusual to obtain a family history of eighteen individuals in four generations affected with the disorder. Doubtless among French-Canadians, whose fecundity is proverbial, the proportion of the diseased to the healthy is not excessive, nevertheless the report loses little of its interest on this account.

In obtaining the family history from the wife of one of the patients, precautions were taken to corroborate her statements by questioning the neighbors, and comparing her story with the account given by the first patient examined. The memory of the latter could not be relied upon, but his narration, as far as it went, agreed perfectly with that related by his sister-in-law, who furnished further details.

Jean Baptiste J., farmer, was the first member of the family affected, as far as can be ascertained. The trouble began late in life, and after having suffered from typical choreic movements for twelve years, he died at the age of eighty years. He was married and had a family of fourteen, and of these five daughters and one son were seized with the same malady.

Taking these children in turn, we come to the second case, Mme. P., who died at an advanced age, showing, besides the movements, well-marked mental symptoms. The onset of the trouble was in her forty-seventh year, and she became gradually worse for some ten or twelve years, when she was removed to the asylum at Longue Pointe. She was married and had a family of eight, all healthy so far as is known.

The third case, Mme. D., also died at the asylum at about eighty years of age. She had suffered for some ten years before admission to the institution, and lived for five or six years after being immured. The number of her family could not be definitely ascertained, but it was large, and one male was affected.

The fourth case, Mme. B., has a history very similar, for she died five years after being placed in the asylum, at the age of seventy-five years. She had a large family, all healthy.

Mme. R., the fifth case, died at the age of sixty-five years, after suffering for fifteen years from choreiform movements. The mental disturbance was not marked. She was married and had one son and two daughters. Of these one daughter had the disease, and she in turn had a son and daughter affected.

Mme. C., the sixth case, died at the age of seventy-seven years, after having had well marked movements for twenty years. She had eighteen children, and of these six males have chorea.

J. B. J., junior, the seventh case, is the only one giving a doubtful history. He was the youngest child, and at present is some forty years of age. He began to be troubled with jerking movements of the arms and face which continued to be well marked for two years. He consulted some physician shortly after the onset, who put him on tonic treatment with the happy result, or coincidence, of the entire cessation of the manifestations of the disease, and from this time he has been perfectly well. He is married and has six healthy children.

Thus far we have been dealing with the family of J. B. J., senior. Let us now turn to their children.

The eighth case, son of Mme. D., became affected at the age of twenty-five years, and he is known to have had well-marked twitchings of the extremities for several years before leaving for the United States twelve years ago. Nothing further can be discovered of his subsequent history.

The ninth case, a daughter of Mme. R., died at the age of forty-five years. The movements had been very violent for fifteen years before death, and they were said to have been first noticed at the age of twenty-five years. She was married and had one son and one daughter with the disease.

Joseph C., the tenth case, oldest son of Mme. C., is a man aged sixty-five years, and for the past ten years has had the typical symptoms of Huntingdon's chorea, while for several years he has been mentally weak. He is married, but has no children.

The eleventh case, Jean Baptiste C., son of Mme. C., was first seen and examined on April 16, 1904. He is a farmer, aged sixty-three years, married, with a family of eighteen children, with no history of rheumatism, tonsillitis or chorea. As a young man he was considered to have exceptional ability, although uneducated. His general health is good and his appetite hearty, as he is hungry "all the time" and very fond of dainties. The present trouble began some twenty years ago when his wife noticed that he was unusually loquacious, and anxious to lead the conversation upon every occasion, at the same time he became restless at night, and very soon movements began in all four extremities, although at first the arms appeared to be more affected than the legs. The twitching was invariably increased at night. Shortly afterward he became capricious and easily angered, also quite malicious, pinching his wife intolerably. He speedily became worse and his whole body and face began to jerk as well as the extremities, his speech became incoherent, his memory failed and he began to have peculiar ideas, at times he was unmanageable and would not wash himself or permit any one to touch him for this purpose. He has not done any work for fifteen years and even before this time he was useless for hard labor.

Examination.—The patient is of slight build, rather under middle height and somewhat

stooped. Musculature is below the average, complexion clear, hair gray. He has a sly, silly expression, and winks and nods as if having a joke at the expense of one of the company. His movements are bizarre in the extreme and are exaggerated when in the presence of strangers. His body twists in and out at the hips and knees, and his feet shuffle as he staggers round the room like a drunken man, while his hands, wrists, and arms are continually writhing and jumping with a motion which suggests a combination of athetosis and chorea. At the same time the expression of his face changes from a smile and a wink to a silly vacant stare or a look of low cunning. The movements are said to come on at intervals during sleep, frequently without waking him.

The gait is sluggish, awkward and staggering, and he walks with a broad base, although rarely with his eyes directed to the ground. The will seems to have but little influence upon the movements, and the state of his clothes amply testifies to the fact that he spills most of his food while conveying it to his mouth. His mental condition is peculiar in that he has intervals during which his memory is fairly good, and frequently at such times he realizes his present state and melts into tears pitying his miserable lot. Then follows a period of indifference and subsequently he becomes smiling and jolly, then boisterous, with a desire to be mischievous, but even in his more violent moods he is easily frightened. During one examination lasting about two hours he showed all the phases above mentioned. At times he has strange fancies, as, for example, about a year and a half ago he began to grow a beard, although he had been clean shaven all his life. On being asked his reason, he said that Christ died with a full beard, and that if he died in the same condition he would also go directly to Heaven.

His speech is markedly indistinct and muttering, and very difficult to understand. It is also jerking, though not syllabic, several words being ejected at a time, frequently followed by a cough or contortion of the face. His articulation varies a good deal with his state of mind, for while in a rational mood every word was enunciated with distinctness, a little later none but his wife and intimate friends could understand what he meant.

He appears to understand very well what is said to him, and makes great efforts when asked if he remembers a name or event, and if given time is occasionally able to recall the required information. He has never been able to read or write, so that these functions could not be tested. His sleep is poor and very much interrupted by the movements, although, as before mentioned, he often remains asleep while they are going on. The muscles are small, but firm, and their voluntary power fairly good. His grip is irregular and much increased during spasm. Sensation, as far as one can judge, is normal. The knee-jerks are active, and there is no ankle or rectus clonus. There is no Rhomberg's sign. He is able to swallow without difficult, once food has reached his mouth. His eyes are clear, blue in color, and the pupils are equal, normal in size, and react to light and accommodation. There is no nystagmus. The pulse is of good volume and tension, regular, and the arteries are in fairly good condition for a man of sixty-three years.

The twelfth case, Basil C., a man of fifty-four years, has shown definite signs of the disorder, in movements of the extremities, for the past six years. He is married and has two girls and one boy in good health.

The thirteenth case, Francois C., was the first of the series to come under observation. He presented himself at the Neurological Out-Door Clinic of the Royal Victoria Hospital, Montreal, on December 17, 1903, and his history at once prompted an excursion to his native village to examine into the truth of his statements. He is a man forty-nine years of age, married, with eleven healthy children. He enjoyed good health until ten years ago, when he suffered with severe headaches, which continued off and on until the beginning of the present illness, some four years ago. The patient's habits are regular, he has taken alcohol in moderation and denies all venereal trouble.

The movements were first seen in the legs, soon followed by involvement of the arms and face. The onset was quite slow, and the patient has seen little or no change during the past three years. The movements are worse at night, and sleeplessness is the most annoying symptom.

Examination.—The patient is a man of medium size, fairly good musculature, and looks rather older than the age stated. His expression is intelligent, though at times ludicrous from the contortions produced by the disease. There is an almost constant jerking of the shoulders, upper arms, head and neck. The hands are comparatively steady, and the facial muscles remain free from movements for several minutes at a time. The legs are also fairly steady while the patient remains seated, but the gait is slightly staggering when he attempts to walk about. The extremities on the left side are more markedly involved than those on the right. Voluntary power is good, but the grip is always increased with each spasm, and in consequence is irregular. There is a certain amount of voluntary control of the movements, and co-ordination is good. There is no Rhomberg's sign, and no disturbance of sensation. The knee-jerks are active and the plantar reflex normal. There is no ankle or rectus clonus. The pupils are equal, of normal size, and react to light and accommodation. The external muscles are normal, and there is no nystagmus.

The cardiovascular and other systems are normal. The mental condition is fairly good, but the memory is defective and his relations state that he is becoming somewhat unreasonable and irritable when at home. This patient has been kept under observation for the past five months, and has shown but little change for better or worse. A small dose of bromide at night has enabled him to sleep better, but treatment has, as usual, been of no permanent value.

The fourteenth case, Narcisse C., aged fifty-three years, is one of the most interesting of the group. The first signs were noticed at an early age, for the symptoms have been present for over twenty years. He became violent very soon after the onset, and jealousy of his wife appeared the first notable evidence of mental derangement. He frequently flew into violent passions, and on one occasion when at church he pulled his wife around the building by the hair of her head, much to the consternation of the peaceful "habitants." He was confined in the asylum, but managed to escape, and for eighteen days nothing was heard of him, but he gradually worked his way from Quebec to Montreal, a distance of 180 miles, and suddenly appeared among his relatives, accusing them of immuring him without cause. He soon returned to his old habits of violence, and was once more placed in the asylum, where he still remains. He had fourteen children, twelve of whom are living, but they were sent away from home, as the mother thought that the disease was catching, and their present condition is not known.

Antoine C., the fifteenth case, is about thirty years old, and has had the movements for three years. He has a family of eight, all in good health.

The following three cases have appeared in the fourth generation:

The sixteenth case, a granddaughter of Mme. R., affected at the early age of twenty, has had the disease for about two years.

The seventeenth case, her brother, about one year younger, developed the movements about the same time.

The eighteenth case, Jean Baptiste C., Jr., son of J. B. C., has just begun to show signs of the disease, and is the third case examined. He is a young man, aged twenty-six years, a farmer, single, and has always enjoyed good health, although never robust, heavy labor being very fatiguing. The trouble began to manifest itself about a year ago, when muscular twitchings of the arms, with restlessness, were noticed at night. His sleep became disturbed, and he would frequently wake up at night with the jerking of his body and extremities. He has become slightly but gradually worse, and at present the movements occur at intervals in the daytime, as well as at night.

Examination.—The patient resembled his father in build and musculature, in that he is slight and below the middle height. His face has rather a sullen expression and he looks rather stupid, chiefly on account of the position of his eyelids, which are kept half closed. The lids are constantly winking, giving him the appearance so characteristic of albinos, when they are exposed to bright daylight. This peculiarity was well demonstrated a short time ago, when he had his photograph taken, for in all the negatives his eyes were closed as if he were asleep. His gait is normal, although rather slow and careful for a man of his age. A few twitching movements of the left arm and the strange rapid winking of the eyelids are all the motor phenomena noticed in the examination during the daytime, the muscular power being good.

In answering questions the speech is slow and he seems to require a little time to think before replying, but articulation is perfect and uninterrupted. The knee-jerks are present and there is no clonus. His eyes are blue and the amount of pigment in the iris appears to be normal. The pupils are equal, of normal size, and react to light and accommodation, and the external muscles are functionally perfect. There is no nystagmus. The other symptoms are normal.

There are a few points of interest in the series which may be worthy of attention. First, the number of children in the families. The occurrence of Huntingdon's chorea in large families was pointed out some years ago, but in the case of French-Canadians ten or fifteen children is not at all an unusual number, and I think that little stress can be placed upon this point. Then the descendants appear to develop the symptoms earlier than their parents. This is not usually an accepted characteristic of hereditary chorea, but it seems to be fairly constant in this series. Of course, the contention may with truth be urged that a great many of the children are yet young, and may still become affected, thus raising the proportion. The distribution among males and females is, as usual, about the same, and no cases were found in which a generation had been skipped. The increase in violence of the twitching at night with resulting sleeplessness, in these patients examined, was very marked, and indeed the most distressing symptom, this together with the continuance of the movements during sleep, though not unknown, is not usual.

The pathology of Huntingdon's chorea is quite as indefinite as that of Sydenham's chorea, and the many findings by different investigators seem to leave us in as great darkness as before, but I think that the hint given by Sir W. Gowers in his able article on abiotrophy should form a solid foundation for future study. The occurrence of the disease in groups which have the tie of consanguinity, the slow development of the symptoms, usually in middle life, the absence of adequate cause, and the correspondence of the outward manifestations to the functions of the cortex, all point to an inherent defect in vitality of the structures forming the gray matter of the brain; while the comparative or absolute freedom from disease of the rest of the body suggests that the disease is limited to this definite group of cells. These points justify the designation "abiotic" to this disease, and by fully understanding the term we can form a definite idea of the course and prognosis of the malady.

Evidently the whole cortex is not involved at once, nor is it always involved in the same manner, as in one of the cases cited the mental symptoms were among the first to appear and they became greater as the process advanced, while the motor symptoms were subordinate. In another case the advance upon the arm and face areas were subsequent to a well-marked speech dis-

turbance which might well be due to changes in the phychic areas. In a third case the legs were primarily affected, although the arms and head very soon showed a greater agitation. These facts point to a general involvement of similar neurons or parts of neurons, advancing gradually, according to the lines of the least resistance.

Treatment in all conditions of this kind must from the very nature of the process be unsatisfactory, but a few cases appear to have been arrested spontaneously or otherwise, and the history of No. 7, the only doubtful case of this series, may offer some slight encouragement for one to attempt to check the progress of this form of abiotrophy of the nervous system.

INFLUENZA IN CHILDREN.

BY KENNETH E. KELLOGG, M.D.,
OF NEW BRITAIN, CONN.

It is not over fourteen years since the first extensive epidemic of influenza overran this country, and since that time the disease has been more or less constantly with us. It was at first considered by the medical profession of little more importance than an ordinary coryza. From that time until this, however, we have grown more and more to look upon it as an exceedingly serious condition, until now, when we realize that instead of a local and temporary process, it is a universal affection and far reaching in its effects. It is probable that even at the present time many laymen fail to realize the fact that influenza is a highly contagious affection, and one of the most virulent of the acute specific diseases.

In addition to the reviewing of the general manifestations of the disease as it appears in children, and outlining the general treatment, it is the object of this paper to emphasize the extreme seriousness of the condition and to make a plea for the enlightenment, *through the medical man*, of the *public* on the question.

The disease as it exists in children presents a somewhat different aspect and runs oftentimes a more protracted course than in adults. The Cannon-Pfeiffer bacillus, which is admittedly the specific cause of the disease, is a small, slender, non-sporing, non-motile, aerobic organism which has the peculiarity of developing only upon cultures which contain blood-coloring matter.

The germ has very little capacity for life outside the diseased body, dies very quickly in water, and is destroyed by rapid drying. Therefore it is believed that it is not propagated by the air or water as much as it is carried by the catarrhal secretions from the afflicted patient. Other organisms, especially the pneumococcus and streptococcus, are often associated with the influenza bacillus, both in the acute and chronic cases. Pfeiffer has said that the influenza bacillus may be found in the catarrhal secretions many months after the disease has apparently subsided. Under certain conditions, therefore, the excitant with which to start an epidemic is frequently present.

The detection of the influenza bacillus in the sputum or in the blood, would appear as important a factor in the diagnosis of influenza as the demonstration of the tubercle bacillus in tuberculosis or the diphtheria bacillus in diphtheria.[1] Whereas bacterial diagnosis is not a simple process, it is sufficiently definite to allow of its being resorted to by the general practitioner. In fact, the bacterial diagnosis of the influenza bacillus involves a less complicated technic than does the study of the tubercle bacillus.

While we are accustomed to think of the nasal mucous membrane as the home of the influenza bacillus, it is becoming more and more evident that this micro-organism behaves like so many others, that it wanders, and has been found in many tissues, both during life and at autopsy. Thus the germ has been found by Hogersted in the pericardium and endocardium, and by Flexner in the central nervous system, and Abbott claims that it has been detected in the bodies of the leucocytes.

The catarrhal symptoms are probably due to the presence of the bacillus itself, and the immediate effects of the toxin are shown by symptoms directly referable to the cerebrospinal center. The remote effects are manifested by the lowered tone of the nervous system and other tissues, producing in the patient a predisposition to many subsequent diseases.[2]

At autopsies of patients dying from the disease the nervous system is found much congested. There does not seem to exist any immunity to the disease, for all ages are susceptible. Much depends, however, upon the vital resistance of the individual, and upon the previous condition of the mucous membranes.

Three types of influenza have been described by some observers, as follows: The nervous type, the gastro-intestinal type and the respiratory type. Frequently one or more of these exist in combination, so that the disease, at times, assumes many phases and is exceedingly difficult to recognize, so that only by process of exclusion can one arrive at a correct diagnosis.

Holt, in 1895, at an annual meeting of the American Pediatric Society, reported a fatal case in a young infant, although he fails to mention it in his text-book.

Kerley, of New York, reports two fatal cases occurring in young infants.

Case I.—James F., aged six months, healthy, steadily gaining in weight, was taken suddenly with a cough, diarrhea and vomiting. Temperature first day from 99° to 101° F., second day from 99° to 101° F., third day from 103° to 105° F., fourth day from 101° to 103° F. Died on the evening of the fourth day.

Case II.—Child, aged fifteen months. Previous history negative, gaining steadily in weight, was taken suddenly with diarrhea, vomiting and a slight cough. Temperature first day from 102° to 103° F., second day from 103° to 104° F., third day from 101° to 101.6° F. Died on the evening of the third day.

Physical examination in both of these cases revealed only a mild bronchitis. The gastro-intestinal symptoms were those of a mild catarrh. The infants were both severely prostrated from the first and lay in a semi-comatose condition, presenting the appearance of having been stricken with a most violent poison; pulse 150 and upward, until it could not be counted; eyes sunken and rolled up; pallor extreme; face drawn and pinched; pupils dilated and muscular twitchings present. Both children were carefully watched by their nurses so that drugging was out of the question. These two cases exemplify the severe nervous system type.

In addition to the commoner symptoms of an acute catarrhal inflammation which are usually, but not always, present, there exists a band of redness upon the palatine arch, the uvula and tonsils not, as a rule, being involved. Again there is frequently present an enlargement of the papillæ of the anterior portion of the tongue.

The catarrhal symptoms are not so universal in the child as they are in the adult, but in a measure are characteristic, and are usually accompanied by an enlargement of the cervical and submaxillary glands. The fever of influenza is a strikingly irregular one, being sometimes present, sometimes absent, high in the morning and low in the evening on one day and vice versa on the next. In fact, the disease may run its course with a subnormal temperature, and in infants this is fairly common. There is a type of the disease which runs a continuous fever for a number of weeks. This simulates more or less closely typhoid fever.

Grippal infections of the small bronchial tubes in feeble infants is a very serious complication. It manifests itself by great dyspnea and cyanosis, the respiratory murmur at times being hardly audible. This infection of the lung tissue, however, is not common.

In the nervous type there appears to be more or less of a constant symptom-complex shown by peevish actions on the part of the child and the manifesting of a desire to be let alone, while it exhibits an irritability combined with an aching of the limbs shown by crying when being held or pressed upon, drowsiness, and occasionally symptoms of meningeal irritation, such as slight muscular twitchings, or sometimes well marked convulsions may be present. The temperature runs an irregular course, varying from subnormal to 106° F. The respirations may be rapid and accompanied at times by cyanosis. The prostration appears to be out of all proportion to the other symptoms, and may be extreme from the first.

The gastro-intestinal infection is evidenced by vomiting and diarrhea, being as a rule not serious; on the other hand, indeed, they may be construed as one of Nature's methods of elimination. This effort on the part of Nature is also demonstrated by the occasional eruption which simulates that found in scarlet fever. Purpura not infrequently occurs, and so may edema, both probably toxic in nature.

Many times there is a co-existing catarrhal inflammation of one or more of the accessory sinuses. This, by reason of secondary infection, may result in a purulent inflammation. This condition is evidenced by either the discharge of a mucous or muco-purulent character, especially from one side of the nose, intermittent, but at times profuse. On examination pus is seen discharging beneath the middle turbinated bone. Pain is sometimes elicited by pressure on the supra- or infra-orbital region, and is generally present over the frontal sinus. Occasionally there is marked swelling of the lids and surrounding tissues. A more common complication, however, is an extension into the ear through the Eustachian tube, resulting in a catarrhal or purulent inflammation of that organ. This complication has been a strikingly common one during this winter's epidemic.

The mastoid process is frequently involved, and, owing to the cartilaginous character of the structure of the roof of the ear in infants, an extension into the meninges is by no means rare. Postauricular abscesses are frequently found, and are much more common in children than in adults.

F. Forchheimer has written on the acute dilatation of the heart in children during the course of influenza. He has reported several cases. He believes that there are two forms of dilatation accompanying this disease; one progressively produced by the action of the toxin upon the nervous system and possibly upon the myocardium, and another occurring in conditions materially interfering with the flow of blood because of mechanical obstruction.

Nephritis accompanying influenza in children is a rare complication, but does occasionally exist, and Freeman[3] has reported a case of acute hemorrhagic nephritis following influenza in a four-year-old child.

Miller has subsequently reported forty cases of this nature. I have recently had two cases of acute exudative nephritis accompanying influenza in infants.

A pseudo-pertussis cough accompanying influenza in infants has come to be recognized as a fairly common symptom. This is often of a dry, non-productive, paroxysmal nature, closely resembling that found in whooping-cough. This was first reported by Forchheimer in 1900.

The diagnosis of influenza is usually arrived at, as before stated, by the process of exclusion. It is to be differentiated in children from malaria, measles, scarlet fever, diphtheria, whooping-cough, typhoid fever, pneumonia, ordinary catarrhal inflammation of the mucous membranes, cerebrospinal meningitis, acute inflammation of the lymphoid tissue in the nasopharynx and tonsillitis.

From malaria it is to be differentiated by its irregular course, by the absence of the enlarged spleen and the organisms of Lavaran in the blood, and furthermore the temperature of influenza is as a rule uninfluenced by quinine.

From measles it is to be differentiated by the time, appearance and location of the eruption of

the latter disease, the presence or absence of Koplik's spots, the course of the temperature and the existence in the community of an epidemic of one or more of the affections.[4]

From scarlet fever[5] the disease is to be distinguished by its characteristic eruption, which lasts longer and alternately fades and becomes more distinct, and, as a rule, does not appear as early as the eruption in scarlet fever. The character of the tongue in influenza is different from that seen in scarlet fever. In the former, small elevated purplish papillæ are seen on its anterior portion. Hematologists furthermore tell us that there is a leucocytosis in scarlet fever, while as a rule there is none in influenza.

From diphtheria it is to be distinguished by the absence of the characteristic membrane, but oftentimes it is only by the assistance of a bacterial examination that we are enabled to differentiate between the two diseases. Influenza in many cases begins with a bronchitis. The tongue has the character of the "raspberry tongue," on the palate are spots or stripes; the influenza membrane is yellowish white and is not placed upon a dark red inflamed membrane, as in diphtheria, but upon a tonsil of almost normal color. The membrane is not influenced by antitoxin.

From whooping-cough the absence of fever, the persistent and well-defined whoop and the history of the attack of the latter all serve to assist in the diagnosis.

From typhoid fever it is to be distinguished by its irregular temperature, which frequently is higher in the morning than in the evening, by the absence of the enlarged spleen, by the time of appearance and character of its eruption and by the absence of the positive Widal reaction of typhoid fever. Furthermore, the eruption of influenza covers a larger area and remains longer than that seen in typhoid fever.

From pneumonia it is to be differentiated by the absence of physical signs in the chest and also by the absence of leucocytosis. Furthermore, in pneumonia the characteristic diplococci in the sputum may be recognized by simple staining.

From the ordinary catarrhal inflammation of the mucous membrane it is to be differentiated by the intense prostration which is usually disproportionate to the other symptoms, and also by the presence of glandular swellings.

Cases exhibiting nervous symptoms and indicating meningeal irritation simulate closely cerebrospinal meningitis and only a bacteriological finding will reveal the true nature of the condition.

From acute inflammation of the lymphoid tissues of the naso-pharynx, the disease is to be distinguished by the previous history of the patient. Mouth breathing, disturbed sleep, night terrors, and snoring usually antedate an acute inflammation of the lymphoid tissues. Examination of the throat will frequently reveal the presence of adenoids and enlarged tonsils.

The onset of acute tonsilitis, in differentiation from influenza is more abrupt. The temperature is usually higher from the first, the tonsil is studded with whitish spots, but occasionally it is only by the aid of the microscope that we are enabled to distinguish between the two diseases.

In the treatment of the disease, its serious nature requires prompt and constant attendance, and its communicability calls for isolation. *The reckless exposure of the infected in influenza makes the disease so difficult to eradicate.* The child should be kept in a quiet room of uniform temperature and visitors or unnecessary attendants excluded. He should also be protected against drafts and chilling of the skin, but at the same time should be allowed plenty of fresh, pure air. The excretions should be received in strong antiseptic solutions, which should also be applied to the spoons, forks and plates. The patient should not remain too long a time in one room in order that reinfection may be prevented. The room should be thoroughly aired and disinfected after his departure. Owing to the intense depression of the nervous system, the rest should be complete and prompt and stimulating treatment administered from the first.

If suffering from an attack of a severely toxic nature the child should not be lifted or carried in the upright position. The function of elimination should be stimulated; the bowels freely opened by split doses of calomel, with or without castor oil, plenty of water given to promote diuresis, and at the outset a diaphoretic, in the form of a hot acidulous drink, should be administered. Hydrotherapeutic measures should be used; dry or moist heat, hot water or steam baths, or hot packs every few hours until a free diaphoresis is established. If the fever is high the cold pack may be superior, at the same time the feet and hands should be kept warm by hot water bottles or mustard baths. This cold pack might well be followed by a saline rectal injection.

To allay the nervous and muscular manifestations in the sthenic cases, phenacetin appears more desirable than opium. It should be given, of course, in small repeated doses. It is prompt in its action, has no cumulative effects, does not produce gastric disturbances, and has probably the least depressing effect of any of the antipyretics. In cases of collapse and evidences of toxemia a saline injection, as before mentioned, will tend to tide the patient over a critical period. *All measures which serve to depress the nervous system cannot be too strongly condemned. The stronger coal tar products, such as acetanalid, being distinctly contra-indicated.* The nerve depressing action of the toxins upon the great centers and upon the cardiac muscle prohibit the use of such drugs. The routine use of strychnine appears to be an important adjunct in the treatment of all these cases. I believe, however, that the condition frequently justifies much larger doses than are usually given.

The elimination of toxins through various channels should be constantly stimulated. It is possible that the coryza, the diarrhea and the eruption are simply expressions of Nature's effort of

elimination, and this effort we should respect and encourage rather than discourage. For this reason the writer does not believe in the routine use of opium in all cases, but only in those whose eliminative processes are otherwise sufficiently active.

Salipyrine is considered by a number of eminent authorities to be almost a specific in influenza in children. They give from two to four grains to a child from five to ten years old. Inasmuch as this drug, however, contains antipyrine it would seem to the writer much inferior to phenacetin.

For the catarrhal symptoms, and with a possible view of limiting an extension, a saline nasopharyngeal spray will be of service. In the administration of this spray, however, extreme caution must be observed lest infection be conveyed through the Eustachian tube. To avoid this the child's head should be turned upon its side and the uppermost nostril sprayed. The position should then be reversed and the procedure repeated. To combat a decided turgescence of the mucous membrane of the nose and throat an adrenalin chloride solution will allow a freer respiration and possibly limit an extension into the Eustachian tube and subsequent ear abscess.

When symptoms of ear involvment appear, and especially if bulging of the membrane occurs, a free and early incision followed by a mild and gentle irrigation of a warm bichloride solution should be practised. Where the symptoms of ear inflammation are exceedingly mild the use of an ice-cap, and the application of leeches in some cases may be permissible, serving to limit the process, but in the vast majority of instances an early incision is necessary. Lanolin, in which is incorporated ichthyol, appears to be especially beneficial to the glandular swellings of influenza. The bronchopneumonia and gastro-intestinal types call for treatment which is little different from the treatment of these conditions when not produced by influenza. Cases running a subacute course are frequently benefited by a change of air.

I think it is now generally accepted that many acute infections; rheumatic fever, measles, scarlet fever, whooping-cough, influenza and others gain entrance into the system through the lymphoid tissues. Consequently it behooves us, as a preventive measure, to see to it that our children's throats are kept in as nearly normal condition as possible, to have adenoids and hypertrophied tonsils removed when they are sufficiently large to produce symptoms, in order that the subsequent infections may be at least modified in severity if not altogether prevented.

The children should sleep in well-ventilated rooms; rooms exposed to the sunshine and fresh air by day and those which allow plenty of fresh flowing air by night. They should be properly but not overclothed, their wrists, hands and feet should be kept constantly warm, they should receive plain but nourishing food at regular intervals, their stomachs should be kept in the best possible condition, they should abstain from sweets, tea and coffee, and should be allowed to spend a number of hours each pleasant day out of doors. Fatigue, however, should be prevented.

During recent years the morbidity of tuberculosis has increased in a measure, no doubt owing to the vulnerability of the mucous membrane following grip. In many postinfluenzal glandular swellings in children is the tubercle bacillus waiting only for an exciting cause when it may multiply and in time produce a fatal tuberculosis.

In dealing with a disease which may be so profound in its immediate, far reaching and disastrous in its remote effects, it is the duty of the members of the profession, who are guardians of the public health, to sound a warning note, especially during epidemics; to teach the public to look upon the disease in its true light; to teach that it is a highly communicable disease, a disease that at any time may assume a rapidly serious aspect; a disease which produces a fertile soil for many subsequent infections; and one which may result in chronic invalidism.

How few mothers are aware that their little one suffering from a pulmonary tuberculosis or a chronic otitis, or an endocarditis, one or more of the many diseases of childhood, subacute or chronic, has had its way paved by what was first considered "simply a grip cold."

In instituting treatment for the immediate condition we fulfill but half of our duty. Surely preventive medicine is equally important and productive of results as curative, and to no other disease can preventive medicine be applied with richer returns than to influenza.

REPORT OF A CASE OF ADDISON'S DISEASE TREATED BY MEANS OF SUPRARENAL EXTRACT AND ADRENALIN CHLORIDE.

BY DOUGLAS SYMMERS, M.D.,
MEMBER OF THE RESIDENT STAFF OF THE CITY (CHARITY) HOSPITAL, OF NEW YORK.

That portion of the English, French and German literature devoted to the consideration of the so-called specific treatment of Addison's disease by means of preparations of suprarenal gland, has been admirably digested by Dr. Edward W. Adams, of London, whose paper in the *Practitioner* for October, 1903, includes an analysis of 97 cases. It is probably the most complete exposition of the subject in the language.

Seven of the 97 patients were made distinctly worse by the treatment, 43 derived no real benefit, 31 showed marked improvement and 16 were permanently cured. The methods of applying organotherapy in Addison's disease, Dr. Adams groups under five heads. A sixth and newer, but comparatively untried, method follows as a logical sequence and involves the use of such preparations of suprarenal gland as adrenalin chloride.

1. *Suprarenal Grafts.*—Three patients have been treated by this method and all died. One was a child of fourteen, into the cellular struc-

tures of whose abdominal wall the suprarenal glands of a dog were grafted. Death resulted on the third day and was preceded by elevation of temperature and coma. The two other patients received subcutaneous grafts of the suprarenals of a dog in both sides of the abdominal wall, local anesthesia being employed. Both died within twenty-four hours with symptoms of hyperpyrexia and prostration. Such speedily fatal results, while due no doubt, in these three instances, to the effect of the grafts, are not unknown in Addison's disease, no matter what the treatment. Addison himself, and, since his time, Dieulafoy, Anderson, Bradbury and Osler have called attention to the occurrence of sudden death in this condition. Dieulafoy, Anderson and Bradbury have noted the more frequent occurrence of sudden death in Addison's disease without pigmentation.

2. *Fresh Gland by the Mouth.*—Nine patients have been treated by this method. One became worse, one derived no real benefit, six were markedly improved and one permanently relieved.

3. *Hypodermic and Intramuscular Injection.*—Eleven patients have been so treated. One became worse, six derived no benefit, three were markedly improved and one permanently benefited.

4. *Fluid or Solid Extract of Suprarenal Gland by Mouth.*—Sixty-one patients were treated after this method. Two were made worse, 32 derived no benefit, 17 were markedly improved and ten were permanently relieved.

5. *Mixed Methods.*—Five patients have been so treated. Three were markedly improved and two cured.

6. *Adrenalin Chloride or Similar Preparations of the Active Principle of Suprarenal Gland.*—There is but one recorded case of Addison's disease treated by this method. The case in question is reported by Raven in the *British Medical Journal* for January 16, 1904. The patient was a middle-aged woman who, in 1893, developed some pigmentation of the skin after an attack of scarlet fever. In the course of the next four years the degree of pigmentation increased and she suffered numerous syncopal attacks, diarrhea and vomiting. In 1901 she was treated by tablets of the extract of suprarenal gland. Finally she had a number of convulsions, the pulse became very rapid and small and coma supervened. The pigmentation was now quite general and involved the buccal and other mucous membranes, and emaciation was marked. The heart sounds, however, were good. At this moment she was given five minims of a 1-1,000 solution of adrenalin chloride three times a day, and after a week the pulse became stronger, consciousness returned and the convulsions ceased. After the lapse of two weeks the dose was increased to ten minims three times a day. At the end of a month the pulse was slower and more full, and the pigmentation had distinctly decreased. The dose was increased to 20 minims and then to half a dram three times a day, but had to be reduced now and then. The patient improved steadily and after eleven months was able to indulge in moderate exercise, the pigmentation having faded distinctly and the syncopal attacks and gastro-intestinal disturbances having ceased entirely.

The universal adoption of this or of similar substances in the treatment of Addison's disease would seem to be justified, since they more nearly approach the fulfilment of the ideal method of introducing into the general circulation that principle which is lacking, and upon whose absence the condition described as Addison's disease would seem most likely to depend. However true this may be, there are those who would weight their use with the objection that absorption by mouth does not occur and that hypodermic injection is almost immediately followed by resolution into inert products of oxidation.

Of seventeen fatal cases of Addison's disease where the patients had been subjected to organotherapy, in two the suprarenals were completely absent. Both patients were markedly benefited. In two the suprarenals were shrunken and fibrous. One of these patients benefited greatly, the other derived distinct temporary benefit. In no one of the four patients was any tuberculous change noted. In another patient there was a tuberculous nodule in one kidney and in this case organotherapy afforded great relief. The patient succumbed to tuberculous meningitis. In five of the remaining number caseating foci and sclerotic nodules existed. Three of these patients derived no benefit from suprarenal therapy, the two others were temporarily relieved. In five patients the adrenals were enlarged and caseous with little or no fibroid change. Of these, three derived no benefit, two were temporarily benefited. Two patients, in whom both suprarenals were tuberculous, derived no benefit.

This analysis suggests to Adams that those cases "most likely to derive benefit from specific treatment are those in which the process is a chronic sclerosing one and where the other organs are fairly sound." He does not accept in its entirety Shoemaker's supposition that cases "in which organotherapy is useful are probably those . . . in which a portion of the gland or glands is functionally potent," since in some cases the glands have been found absent, in others reduced to fibrous tissue and yet material benefit has been conferred by the administration of suprarenal extract in one form or another. In those cases in which no benefit accrues from this form of treatment he urges that we should respect the burden under which the method labors when tried on moribund patients, or over too short a period. On the other hand, he would not lose sight of the large number of failures which are never reported. He refers, also, to the apparent recovery of patients long before suprarenal treatment was ever suggested, and to the natural tendency of the disease alternately to remit and exacerbate.

The case I wish to place on record is that of L. Y., white, aged fifty-five years, Hungarian,

musician, married. Family and personal history negative.

Present Illness.—The patient is unable to speak English, and no satisfactory account of his condition can be obtained from him. His wife, however, states that for five months he has complained of pains in the hands and feet, knees, ankles and shoulders, with swelling and loss of function in these parts, and that latterly he has lost greatly in strength and weight. She is not able to fix any definite date for the appearance of the cutaneous pigmentation. Upon admission to the hospital the patient presented, in addition to the more strictly objective symptoms to be outlined below, practically all the subjective manifestations of Addison's disease. Asthenia and emaciation were pronounced. When not constipated he was incontinent of feces. Incontinence of urine was also present. During the three first weeks of his stay in the hospital he suffered from diarrhea. The appetite was indifferent. Vomiting did not occur except toward the close when, within twelve hours, on three occasions, he vomited large quantities of brownish material. The blood examination revealed 2,690,000 erythrocytes and 4,800 leucocytes, 70 per cent. hemoglobin. The urine was of low specific gravity and contained a few hyaline casts but no albumin. The systolic blood pressure, measured by Cook's modification of the Riva-Rocci sphygmomanometer, registered 100 mm. of mercury in the left arm and 140 mm. in the right. It will be observed that at autopsy no change was observed that would account for this difference, which was likewise apparent to the palpating finger. No sputum could be obtained for examination.

The nervous symptoms were rather vague. The patient's mentality pointed to mild dementia—a condition not unknown in Addison's disease. Coarse volitional tremor in the arms was quite noticeable. Percussion beneath the clavicles revealed an excellent response to the pectorohumeral reflex recently described by Mills, of Philadelphia.

Physical Examination.—The patient is an elderly male, profoundly emaciated. For the greater part he is quiet, bordering on listlessness, but at times, particularly when disturbed, becomes noisy and demonstrative. The legs are strongly flexed on the thighs and the thighs on the abdomen, the forearms are flexed on the arms and the arms held close to the chest and toward the chin. Voluntary movements in these extremities are limited, forced movements painful. The patient tends always to assume the lateral posture.

Skin.—The skin of the entire body is of a deep brown color. Around the neck, at the waistband, around all the joints of both hands, at the wrists and around all the toes this pigmentation is exaggerated. The penis and scrotum are streaked by bands of blackish pigment deposit, the intervals being white, almost leucodermatous, so that the whole is not unlike the appearance of the leopard's skin. The palms display spots of deep brown pigment. The soles are only faintly discolored. The region of the sacrum and coccyx is involved in diffuse brown pigment deposits, while just above the left posterior superior spine is an area of brownish-black pigmentation the size of a silver dollar. The arms and legs are more deeply pigmented on the anterior than on the posterior surface. The scalp is faintly discolored. The skin in front and behind the shoulders, on the anterior abdominal wall, on the lower part of the back and on the anterior surface of the thighs is dry and finely scaly. On the lower part of the anterior abdominal wall and in the pubic region pigment is deposited in the form of small mole-like spots which are almost black in color. In both flanks, more particularly the left, leucoderma is present. The patch on the left side approaches the shape of an oblong and is three inches in length and an inch in width.

Mucous Membranes.—Conjunctivæ clear. The mucous membrane of the lips and of the buccal cavity exhibits both large and small areas of deep brown pigmentation. On the left border of the tongue and, in lesser degree, on the anterior and posterior surfaces is a large oblong patch of brownish-black discoloration. The mucous membrane of the glans penis is also streaked with black.

Lungs.—Both apices exhibit impaired resonance on percussion. Although the respiratory excursions are shallow auscultation reveals bronchovesicular respiration beneath both clavicles. At the right apex anteriorly a few fine crackling râles are audible.

Heart.—Apex beat neither visible nor palpable. On auscultation the heart sounds in the region of the normal apex beat are barely to be heard, while at the base no heart sounds are distinguishable.

Liver.—Liver dulness extends about two fingers' breadth below the costal slope.

Spleen.—Not palpable.

Pulse.—Right radial pulse more full than left. Pulses synchronous and 90 to the minute. Artery rather hard. Capillary pulse perceptible beneath nails.

Glands.—Superficial lymphatic glands universally enlarged.

Extremities.—Wrists, knees and ankles swollen, hot to the touch, painful on manipulation. No prètibial edema apparent.

Treatment.—On admission the patient was placed in bed and put under treatment for the joint symptoms. When the diagnosis of Addison's disease was made he was ordered ten minims of a 1-1,000 solution of adrenalin chloride three times a day. This was administered hypodermically. After thirteen days the dose was changed to 15 minims of a 1-5,000 solution. This was continued over a period of five days, when he was ordered extract of suprarenal gland in six-grain doses three times a day, or the equivalent of 18 grains daily. This amount was administered for thirty-five days and then increased to 27 grains daily. After seven days this was increased to 36 grains daily, continued at this rate for

twenty-seven days and increased to 45 grains daily and continued at this rate for eleven days. Then the solid extract was discontinued altogether and ten minims of a 1-1,000 solution of adrenalin cholride given hypodermically three times a day for a period of forty-five days, when the patient died with symptoms of pulmonary edema. Thus the patient was under specific treatment for a period of 143 days. At no time was any improvement noticeable.

Autopsy Report.—(Autopsy performed and notes kindly furnished by Dr. Horst Oertel, pathologist to the New York City Hospital). Body about 167 centimeters in height, of delicate frame, very poor musculature, great emaciation. The bones of the face are prominent, rigor mortis in upper extremities is not very marked, but there is very extreme stiffness of knee-joints, so that it is almost impossible to straighten them out. The skin of the entire body is smooth, thin and displays diffuse dark brown discoloration. In some portions there are patches varying in size which are darker than the remainder of the skin, especially in the region of the scrotum and on the abdomen. The same discoloration in patches is found in the mucous membranes, especially that of the tongue, where it is almost black. Upon section there is practically no subcutaneous fat, muscle tissue brownish pale, very dry and atrophic. The abdominal cavity contains no fluid, the serosa of the intestines is pale and shiny, the diaphragm is at the fifth interspace on the left, and the fourth on the right side. The pericardial sac is thin and contains a small amount of blood-tinged fluid. The heart is small, the right side moderately distended and the left side moderately contracted. On opening the right side there is a little fluid blood in the ventricle, and the auriculoventricular opening readily admits three fingers. The left side is empty, and the auriculoventricular opening admits two fingers. The pulmonary valve is delicate and the curtains are fenestrated. The aortic valves exhibit a good deal of thickening at the base, and very pronounced atheromatous degeneration of the aorta exists with the formation of large calcareous patches. The mitral valve is moderately thickened and contracted, the corda tendinæ slightly thickened and shortened. The papillary muscles are pale, thick and short. The coronary vessels are slightly atheromatous, small and very tortuous. The heart muscle is atrophic, firm and brownish pale. The pleural cavity on the left side is empty and shows old and extensive but not very firm adhesions. The left lung shows adhesions between the lobes and is emphysematous. At the apex is an old scar, at the base a few old tubercles. The right lung shows a few adhesions at the apex and a few old tubercles. The lung is emphysematous and edematous. The spleen is bound down by firm adhesions, is slightly enlarged, the surface is steel blue in color, the organ is firm and there is considerable perisplenitis. On section the color is brownish-pale, the trabeculæ are distinct and the Malpighian corpuscles prominent.

Left Suprarenal.—The left suprarenal gland is bound down by firm adhesions to the left side of the spinal column and is irregular and nodular. On removal it cuts with moderate difficulty, and is seen to be transformed into a large cheesy mass, so that very little tissue is to be made out. As a whole the gland is enlarged.

Right Suprarenal.—As a whole the right suprarenal is enlarged and is bound down in the same way as its fellow. On removal it seems to be harder than the left, smaller in size and not so nodular. On section it appears harder and shows distinct cheesy nodules, but more preserved apparently normal tissue. The cortical portion is distinctly pigmented.

Left Kidney.—There is practically no perinephric fat, the size of the kidney is not markedly changed, the consistency is firm, the capsule strips easily, the surface is slightly lobulated, the color is mottled and shows distinct yellow patches. On section the cortex appears thin and irregular, the markings are very distinct, especially at the junction of cortex and medulla, the medullary rays prominent, the medullary portion pale, the vessels firm and thick.

Right Kidney.—The right kidney is slightly smaller than the left. Its consistency is hard. There is a solitary tubercle in the cortex. Otherwise it resembles the left.

The stomach is small, the walls thickened. The organ contains a little greenish, bile-stained fluid. The mucous membrane near the cardiac end is atrophic and shows loss of the rugae, but near the pylorus it is distinctly thickened and the rugae are marked. The whole surface of the mucous membrane is covered by a thick, white, slimy material, beneath which a number of ecchymotic spots appear. The walls of the intestines are very thin and the mucous membrane is atrophic. The mesenteric glands are not involved. The bronchial glands are large and deep black in color, but show no tuberculous involvement. The liver is moderatey enlarged and shows a moderate degree of perihepatitis in patches, the color is mottled, surface smooth and the consistency diminished. On section the central veins appear prominently as deep red spots, the lobules around them are pale and swollen and their outlines indistinct. The pancreas is small, pale and very hard. On section it is seen to be distinctly cirrhotic.

The Brain.—Dura thickened. Calcareous deposits in the falx. The pia is thickened, especially along the frontal lobes. The arteries at the base show patches of advanced endarteritis. The lateral and third ventricles contain a considerable amount of clear colorless fluid. The left corpus striatum contains a few small areas of cystic softening.

Anatomical Diagnosis.—Chronic endocarditis of aortic and mitral valves, advanced atheroma of aorta, brown atrophy of the heart; emphysema and edema of lungs, with few old small tubercles; chronic atrophic splenitis; chronic pleurisy; tuberculosis of suprarenal glands; chronic diffuse nephritis; chronic venous congestion of liver with

marked fatty infiltration; chronic gastritis; chronic enteritis; cystic softening in left corpus striatum, endarteritis obliterans; chronic interstitial pancreatitis; general brown atrophy of skin.

In conclusion, I wish to thank Dr. T. C. Janeway, in whose service at the New York Hospital this patient was observed, for his permission to place the case on record.

THE GASTRO-INTESTINAL CRISIS OF ERYTHEMA EXUDATIVUM; SIMILATING APPENDICITIS.

BY A. M. POND, M.D.,
OF WEBSTER CITY, IOWA.

OSLER defines exudative erythema as a "disease of unknown etiology, with polymorphic skin lesions—hyperemia, edema and hemorrhage—arthritis occasionally, and a variable number of visceral manifestations, of which the most important are the gastro-intestinal crises, endocarditis, pericarditis, acute nephritis and hemorrhage from the mucous membranes."

It is with especial reference to the gastro-intestinal crisis above mentioned that the present paper will have to deal, for its interest to surgeons, because of the marked similarity in some instances to appendicitis.

The condition may present no evidence of any skin lesions; again, it may precede the gastro-intestinal symptoms, and yet again may not appear for several days after the abdominal discomfort. Quite obviously when the skin eruption precedes the attacks of colic with rises of temperature and pulse, the temptation will not be great to operate for a supposed disturbance of the abdominal contents; but where the eruption does not occur at all, or in cases where its appearance is delayed for several days following the attacks of abdominal pain, and where the temperature and pulse are high and the vomiting continuous, the condition is perplexing.

These gastro-intestinal crises seem to be a very important and quite a constant symptom. In a series of 29 cases reported by Osler the gastro-intestinal symptoms were noted in 25 cases, or 86.2 per cent., and in one instance (*Case XX*) a diagnosis of appendicitis was made and the patient admitted to the surgical service of the hospital, even after the rash had appeared.

Below I report a case in which the eruption did not appear until several days after the intestinal symptoms had become grave:

Ethel B., aged nine years, poorly nourished, anemic. Father, farmer; gives history of severe attack of rheumatism, no heart lesion, and at present no joint symptom; no evidence of kidney disease. Mother died of hemorrhagic pancreatitis in May, 1903; had four children; one died at four months, imperfect closure of the foramen ovule; a brother of mother died of intestinal perforation during typhoid in July, 1902; mother's father died of pneumonia in March, 1902; mother's mother has had rheumatism for many years, no heart lesion, nor evidence of nephritis. Has attacks of skin eruption, erythematous in nature, more frequent during winter months.

January 15, 1904. Complained of headache upon retiring; was given 15 c.c. of castor oil.

January 16. Bowels moved three or four times; began vomiting about noon; complained of severe pain about umbilical region at 2 P.M. Temperature 103° F. 5 P.M., temperature, 103.5° F.; 8 P.M., temperature, 102° F.; father had used hot applications, which seemed to increase the symptoms.

January 17, at 4 P.M. saw the case. Temperature, 104° F.; pulse, 120; moaning and groaning; listless, anxious facial expression; vomited six times since noon. Pain was located a little below and to the right of umbilicus; pressure increased pain materially, and a distinct spasm of the wall of abdominal rectus could be felt; no pain in left groin, pressure tolerated. Ice-bag was ordered over right groin, and pancreatin and soda bicarb. each .0324 gm. ordered p. r. n. for nausea and vomiting. All food by mouth discontinued; liq. peptone by rectum, three hours.

January 18, 9 A.M. Temperature, 98.6° F.; pulse, 110; slept poorly, but complains of no pain, playing with doll; tongue very red and furrowed, gums spongy and bleeding easily. Blood count, hemoglobin 80 per cent.; red cells, 4,136,000; white cells, 10,680. Advised removal to Mercy Hospital, Webster City.

The following record is taken from the history sheet of hospital:

January 19, 12 M., admitted. Temperature, 101° F.; pulse, 100. Pain severe. Ice applied over right groin. 1 P.M., fed per rectum. 2 P.M., sleeping; 4 P.M., moaning in sleep; fed per rectum. 8 P.M., temperature, 101° F.; pulse, 100; respiration, 20. 11 P.M., moans and cries in sleep; restless.

January 20, 3 A.M. Temperature, 100.6° F.; pulse, 100. 8 A.M., temperature, 100° F.; pulse, 89. 11.30 A.M., temperature, 99.6° F.; pulse, 88. 1.30 P.M., temperature, 99.6° F.; pulse, 88; patient very comfortable. 8 P.M., temperature, 100° F.; pulse, 86; respiration, 24; urine, 178 cc.; pain very severe. 10 P.M., temperature, 99.8° F.; pulse, 90; respiration, 16; moaning and crying.

January 21, 2.30 A.M. Temperature, 99.2° F.; pulse, 104; respiration, 16; pain very severe. 3 A.M., expelled gas freely. 5 A.M., temperature, 99° F.; pulse, 96; respiration, 16. 8 A.M., red blotches on face and hands; temperature, 99.5° F.; pulse, 88. Skin eruption was first evident on the right side of face, and consisted of large bright red wheals; the color did not disappear on pressure. 12 M., temperature, 99.4° F.; pulse, 88; pain very severe. 3 P.M., sleeping, but very nervous. 5.25 P.M., rash over entire face, extending down to the neck, chest and arms; several small punctate eruptions capped with a vesical, some containing clear fluid, others substance looking very much like pus; pain very severe; urinated 475 cc. Examination of urine: Color, dark straw; turbid; acid reaction; specific gravity, 1,018; chlorides, 12 per cent.; phosphates, 8.5;

sulphates, 3.5; albumin, 2.5; urea, 1.5. Number of slides examined, 2; fine granular and bloody casts; blood cells; amorphous urates; calcium oxalate crystals. 8 P.M., pain very severe; expelled some gas. Spr. aetheris nit., .92 cc. ordered.

January 22, 3 A.M. Temperature, 98.6° F.; pulse, 90; respiration, 20. 10 A.M., temperature, 99.2° F.; pulse, 88; eruption symmetrically arranged in large wheals over surface of both thighs, an occasional punctate eruption capped with white vesicles, no edema of ankles, no joint pains. Heart apex about fifth interspace, about 7 cm. midsternum, no murmurs; eyes puffy; hydrg. chlor. mitis. 0.0130 gm. ordered every half hour for five doses. 3 P.M., urinated 10 ounces, no pain; examination essentially same as before. 10 P.M., large, free bowel movement, clay color, nor formed, containing blood and mucus; no pain.

January 23, 10 A.M. Child appears listless, indifferent, rash disappearing; pustules forming in right hand; abdomen not tender; tongue red but smooth; gums normal; no puffiness of eyes; urine, 150 c.c.; cloudy, with distinct reddish cast; temperature, 98.6° F.; pulse, 70; soft diet ordered, with soln. pept. ferri et mangan, 4 cm. t.i.d., after meals.

January 26, 2 P.M. Temperature, 98.6° F.; pulse, 76; discharged from hospital.

When this case first came under observation, with temperature of 104° F., pulse of 120, recurrent vomiting, and spasm of rectus abdominal muscle, I at once thought of appendicitis, and this was further confirmed by the blood examination, which showed a slight leucocytosis of 10,680, and had the acute symptoms not subsided by the withdrawal of food by mouth and the application of ice to the right groin, I most certainly should have operated the case at once. But since the child had been sick for forty-eight hours before I had seen her, I thought it wise to pursue means to abate the condition, and after a return to normal temperature and pulse and a cessation of pain, to do a late operation.

After the appearance of the eruption, which, as the record shows, occurred coincidentally with the subsidence of pain and lowered temperature and pulse, etc., the condition was most perplexing. Then with the suppression of urine and the consequential findings in the urine that was passed, of blood, casts and albumin, served to clear the condition somewhat.

It is interesting to note the family history in connection with this case, there being a history of rheumatism, with its allied complications, in three generations. Osler reports one case in which he was able to follow these conditions in five generations.

After the child began to recover, and after a return to normal temperature, pulse rate and cessation of pain, I again examined the abdomen. I could not quite bring myself to believe that there was not some serious pathological condition in the abdomen that was responsible for the grave symptoms that had occurred; the child was thin, and the abdominal walls lax, so that examination was very easy, and the findings reasonably certain.

With the child lying on her back, and the left hand lifting the right loin and making deep digital pressure over the right lower quadrant, no mass could be detected, no point of tenderness encountered, and no swollen or sensitive appendix perceptible, although I am quite sure I could feel it slipping beneath the fingers of my right hand while making a rubbing motion toward the ilium at deep pressure.

Osler accounts for these gastro-intestinal crises as being "probably due to localized edema of the gastro-intestinal walls," and classed these cases with those of angioneurotic edema in which colic occurs as so prominent and constant a feature.

In casting about over the voluminous literature that has recently appeared concerning appendicitis in all of its phases, it is surprising that so little mention is made of these symptoms which are so similar. No one has evidently described the pathology, if he has been unfortunate enough to operate these cases, or else there is a striking similarity of pathology in the cases that appear without any skin manifestations, and are beyond peradventure appendicitis, and those cases in which preceding the operation, or shortly after it, the erythematous condition is manifest.

Many queries concerning this case suggest themselves:

1. Was the skin manifestation in this case similar to the well-known skin complication occasionally found in cholelithiasis?

2. Could it be due to metabolic disturbance similar to the conditions met with in individuals who are susceptible to certain articles of diet, such as shellfish, certain fruits, etc.?

3. Could it be a manifestation of the bacteria concerned in appendix inflammation, especially the *Bacilli coli communis?*

4. Was the abdominal symptom concommitant with the skin lesion as a prominent and constant feature or vice versa?

In discussing the first query, it will be remembered that the erythema co-incident with cholelithiasis is accompanied with intolerable itching and more or less marked gastro-intestinal disturbance, and is commonly of the discrete wheal formation, non-elevated, and disappearing upon pressure. There may or may not be jaundice; if the biliary passages are obstructed, either by mucous membrane inflammation sufficient to occlude the lumen of the duct, or by the presence of a gall-stone of such size as to be unable to pass the duct, jaundice may be present, and, after its subsidence, cause the itching, which, in turn, may be followed by the wheals. The erythema due to some idiosyncrasy regarding the eating of fruit, obviously occurs during the season when such fruit is in abundance, and becomes a portion of the diet. A history of such idiosyncrasy can as a rule be readily obtained, and the condition can be cleared up. The eruption occurs in a fine erythematous rash arranged in patches, and is accompanied by itching.

3. It is hardly reasonable to suppose that such a polymorphous erythema would be produced by bacterial invasion without more clinical manifestations than were noted in the above case. The common bacteria emit a specific toxin peculiar to them, and this toxin has in turn a specific action on the physical economy. Were there but one, or even two distinct types of skin eruption, this might be accounted for by the bacterial cause of some infection, but where the lesions were so varied and numerous it can hardly be considered pertinent.

4. In reviewing the records of this case, and noting the comments made upon this condition by other observers, I am persuaded that the abdominal crisis is a frequent and prominent feature of these cases, of which so little of the pathology is now known. The fact that in some of these cases the gastro-intestinal crises are absent, but present all the polymorphic skin lesions, would argue rather against the assumption that the skin lesion was in any way due to pathology of the abdominal contents, or from any disturbance of the process of metabolism consequential to the pathological process.

From the foregoing it will be readily observed that increased caution will be called for in arriving at a diagnosis in the cases presenting the acute characteristic paroxysms of colic, attended by vomiting, rapid pulse, a tender abdomen, perhaps presenting a tumor, with either a spasm of the abdominal recti muscles, or, in the later stages, a condition of abdominal rigidity.

Typical as these symptoms may appear, to indicate an involvement of the appendix or other abdominal viscera, operative measures should not, I think, be too hurriedly undertaken, without first a careful study of the family history, with the view of discovering skin, joint or kidney lesions in other members of the family, supplementing this with a blood examination and determining the relationship between the red and the white cells, and lastly a thorough examination of the urine, together with an exposure of the surface of the body in search of polymorphic skin lesions.

There are other conditions that may be found that will serve somewhat to clear up matters, such as spongy condition of the gums, which bleed easily on touch perhaps, joint symptoms, areas of angioneurotic edema, with hyperesthesia. In the presence of any of these conditions an early operation is not to be recommended, unless the blood count shows, beyond peradventure, a rapidly increasing leucocytosis; and examinations should be made hourly and the increase be distinct before operation is undertaken.

Bacteriology of Chromidrosis.—R. TROMMSDORF (*Münch. med. Woch.*, July 19, 1904) was able to grow two specific bacteria from a case of chromidrous, the one producing yellow and the other red pigment. The cause of blue perspiration is not yet settled, since some observers have discovered indigo, others ferrous phosphate in the secretion. It is likely, however, that bacteria also play a prominent part here.

MEDICAL PROGRESS.

SURGERY.

Ulcer of the Stomach Due to Lesions in the Gastric Nerves.—It has been claimed that injury to the external nerves of the stomach in animals has been followed by ulceration of the mucous membrane. VEDOVA stated that by causing an injury to the celiac ganglion or its thoracic roots in dogs he was able to produce ulceration of the wall of the stomach which resembled closely the lesion found in the human subject. Van Jizeren also claimed that cutting the vagus below the diaphragm in rabbits was followed by the formation of a chronic peptic ulcer of the stomach. M. DONATI (*Deut. Archiv f. klin. Chir.*, Vol. 73, No. 4) criticizes these views and submits the results of his own experiments in dogs and rabbits, where he resected the vagus below the diaphragm, extirpated the celiac plexus, or did both operations. These attempts were all attended by negative results, and in no instance was there any development or a gastric ulcer or similar lesion. In many animals there was noted an increase in the secretion of hydrochloric acid. The animals were kept under observation for six months. Donati concludes that a trophic origin for the round ulcer of the stomach cannot be conceived, and that this lesion is not due to any changes in the external nerve supply of that organ. He believes, however, that there is a possibility that the nervous system has a certain influence which may act as a predisposing factor, but the processes already outlined are not the only cause which produces an ulcer of the stomach.

Micro-Organisms in the Small Intestine.—It has already been shown that the mucous membrane of the trachea, the conjunctive and the urethra is free from germs under normal conditions, which may be accounted for by the supposition that the mucous membrane has bactericidal properties which destroy the penetrating organisms. I. JUNDEL (*Archiv f. klin. Chir.*, Vol. 73, No. 4) has now also examined the empty small intestine with reference to its bacterial contents, the material for investigation being taken from the gut during the operation for gastro-enterostomy (five cases). In one patient who had a carcinoma of the stomach, the cultures showed numerous bacteria; in two others they were practically sterile. In two cases of benign stenosis of the pylorus, only a few isolated colonies developed, and the contents could be considered sterile. It is evident, therefore, that the small intestine has the power to destroy, soon after it has been emptied, the germs which may be left behind and to bring about a condition which may be designated as an autosterilization. The author asks that further observation be made to verify his statements and conclusions.

The Question of Auto-Intoxication in Ileus.—In order to aid in solving the important question as to whether death in ileus is due to intestinal intoxication or to reflex action, P. CLAIRMONT and E. RANZI (*Archiv f. klin. Chir.*, Vol. 73, No. 3) have carried on a large number of experiments on the toxicity of the intestinal contents. The material to be investigated was secured in large part from dogs, cats and rabbits. The ileus was produced by a circular ligature of the small intestine with a sterile cotton wick, such as is employed for temporary occlusion when doing intestinal anastomosis. Eighty-five animals were thus treated, but in only 81 per cent. were symptoms of ileus elicited. The intestinal contents from the animals and also from a few cases of intestinal obstruction in man, were filtered and injected into other experimental animals. The majority of the animals died, with typical symptoms—diminished respiration, dilated pupils, increased reflex irritability, tonic and clonic convulsions. The symptoms were independ-

ent of the species of animal or the manner of application of the experiments, but seemed to depend on the relation between the amount of the material administered and the weight of the animal. Filtrates of bouillon cultures grown under aerobic conditions all had an equal effect, whereas the filtrates of pure cultures and anaerobic cultures had no effect whatever. The toxic properties of the filtrates were not visibly affected by heating, and keeping them for a time caused them to lose their power spontaneously. A number of these filtrates manifested an hemolytic and cytolytic action (on epithelium) which varied in intensity. The addition of normal brain tissue inhibited the toxic properties of the filtrates, and it seems therefore that these substances form a close union with the central nervous system. Immunization experiments conducted in animals were not attended with any definite results. The authors conclude that in the intestinal contents of cases of intestinal obstruction, whether experimentally produced or otherwise, toxic substances of a bacterial nature are formed, which are absorbed by the system and produce a toxemia. They do not believe that the infection is exclusively with the *Bacillus coli*, as claimed by others. There are probably a number of poisons derived from various micro-organisms of the intestine, which affect the different organs, such as the brain, the heart, the kidneys.

Foreign Body Imbedded in the Heart.—A most unusual case is reported by M. KOCH (*Berl. klin. Woch.*, July 11, 1904), where at the autopsy examination in a man of seventy-six years, who died from inanition due to senility, an elongated steel was found imbedded in the wall of the left ventricle. The patient's history failed to give any clue as to the time of entrance, nor did it apparently cause any symptoms. The object proved to be a needle-like bit of steel about 3 cm. long. It was probably introduced suddenly from without at some remote period of the patient's life, and, strangely enough, never caused any discomfort, and was therefore not noticed.

Pathology of Bullet Wounds of the Stomach.—A case is reported by O. v. FRISCH (*Arch. f. klin. Chir.*, Vol. 73, No. 3), where a laparotomy was done after the patient had been shot in the abdomen. The bullet entered the stomach and the wound was readily found and sutured. The point of exit could not be located, although the X-ray examination had demonstrated that the projectile had traversed the stomach. The patient made a good recovery. The author then made a number of experiments on the stomachs of animals and found that the wound of exit in the serous coat of the stomach was usually a small slit which might easily be overlooked, in those cases where the force of the projectile had been mostly spent. The entrance wound is ordinarily the more extensive and affords the stomach contents an opportunity to find their way into the abdominal cavity. It seems feasible, therefore, not to prolong the search for any wound of exit unless signs of hemorrhage are present, when the wound of entrance is of no greater diameter than 7 to 8 mm., although gastric contents may have been evacuated into the general peritoneal cavity. The abdominal incision may then be closed without danger.

MEDICINE.

Hemalysis Caused by Cancer Extract.—In order to explain the marked deterioration of the blood seen in patients suffering from malignant tumors, D. KULLMANN (*Zeitsch. f. klin. Med.*, Vol. 53) prepared an extract of carcinoma cells and mixed it with freshly-drawn red cells. In every case the cells were rapidly disclosed. Further researches showed that the hemolytic substance is firmly combined in the cells themselves for an unfiltered extract has a stronger action than a filtered one. It is not specific for homologous blood, but dissolves the blood-cells of many species. Furthermore, it is resistant against boiling, is soluble in alcohol and water and not identical with the autolytic ferment of carcinoma or normal organs. After injecting the maceration intraperitoneally another hemolytic substance forms in the animal body, which seems to have a much more complex composition.

Peculiar Course of Cancer of Stomach.—The patient of G. HONIGMANN (*Zeitsch. f. klin. Med.*, Vol. 53) had suffered for years from nervous hyperacidity and had improved considerably under treatment. After an attack of indigestion he developed a severe gastric and intestinal catarrh, which also yielded, except that a moderate degree of atony and supersecretion remained behind. The course was satisfactory and the patient even gained weight, until the entire aspect of the case changed without apparent cause. After a slight gastric hemorrhage, the muscular activity of the stomach ceased completely, the hyperacidity was suddenly replaced by anacidity and attacks of tetany made their appearance. The patient's condition became so serious that an operation was performed, disclosing a pyloric cancer with many miliary metastases in the mesentery. After a gastro-enterostomy the attacks disappeared and the patient enjoyed comparative comfort for eight to ten weeks; but after that the course was steadily downward. The sudden change of the patient's condition after the hemorrhage, the author thinks, was due to perforation of a blood vessel by the growth, thus converting the local disease into a general one. The cause of anacidity in carcinoma is not yet understood and some believe that the alkaline secretion from the ulcerated growth neutralizes the acid. It is, however, more likely that the general intoxication is responsible since the same anacidity is noticed with cancer elsewhere. There is likewise a discrepancy of opinions concerning the cause of tetany, some ascribing it to inspissation of the blood, others to reflex influences or to auto-intoxication, but in this case it was probably due to an inundation of the system with cancer toxins, especially since it has already been proven that the latter may have a specific action upon the nervous system.

Influence of Exercise, etc., on Nephritis.—If patients suffering from chronic interstitial nephritis are placed into a warm or carbonated bath, both blood-pressure and amount of albumin will sink. After the bath, the albumin will often rise, with horizontal posture and fall with exercise. Rest in bed has the same influence as baths, but to a less marked degree, and arteriodilatars, such as amyl nitrite and nitroglycerin, also reduce the albumin, together with the pressure. The beneficial influence of exercise, especially of climbing mountains, without fatigue, is especially emphasized by C. EDEL (*Zeitsch f. klin. Med.*, Vol. 53). The albumin reaches a very low percentage, even though the pressure rises, since increased heart-action accompanies the general dilatation of the vessels. This form of exercise is therefore highly recommended in Bright's disease especially, since it also stimulates the respiration and diminishes the amount of urine.

Diagnosis and Treatment of Azoospermia.—A number of methods have been proposed for determining the presence of living spermatozoa in cases where more or less obliteration of the seminal passages has taken place as the result of a gonorrhea. C. POSNER and J COHN (*Deutsch. med. Woch.*, July 14, 1904) comment on the failure of most of these suggestions when practically applied. Fürbringer has proposed to lay open the tes-

ticle and then to examine the contents. As this is rather an extreme procedure, the writers suggest attaining the same ends by puncture of the testis by means of a hypodermic syringe. There is no pain, an anesthetic is unnecessary and the patients are not confined to bed. When the material obtained is found to be made up of fatty cells and detritus, and spermatozoa are absent, it is of no use to attempt anything more. Where the latter are present, it still remains a question as to what to do. In six cases reported by the authors, the cut end of the vas deferens was implanted directly into the opened canals of the head of the epididymis, or an anastomosis was made by carefully approximating and suturing the edges of openings made in the walls of the vas and the epididymis. In none of these cases, however, were any positive results obtained thus far. The most important thing in this condition is to institute early prophylactic measures, by watching for the development of an epididymitis after the acute gonorrhea has subsided. If present, massage, the application of iodine and other remedies should at once be instituted. It is also essential that frequent examinations of the spermatic fluid should also be made in order to determine its character.

An Instance of Transitory Diabetes.—An interesting case history is presented by E. MANN (*Berl. klin. Woch.*, July 25, 1904). The patient, a man of forty-five years, had been afflicted with a diabetes insipidus, which within a few weeks became converted into a diabetes mellitus, with considerable excretion of sugar. This also disappeared completely within sixteen days under a diet of oatmeal, as recommended by Van Orden. The patient died, however, shortly afterward from a carcinoma of the stomach, in which the pancreas was involved.

Dermatitis Coccidioides.—This disease has been considered identical with blastomycosis. D. W. MONTGOMERY and H. MORROW (*Jour. Cut. Dis.*, August, 1904) have called attention to points of difference between the two. The organism causing coccidioides has a double cycle of growth, one seen in the tissues, the other on culture media, the two having no features in common. Such cycles have not been noted in blastomyces. On agar culture media the aerial hyphæ of the *Coccidioides* organisms are no high and furry; in cultures of *Blastomyces* they frequently are. The growth of the *Coccidioides* organism on agar is sharply circumscribed; that of the *Blastomyces* is not. The micro-organism of *Coccidioides* grows faster and liquefies gelatine more readily than that of the *Blastomyces*. The fungi of each seem to be fatal to the same kind of animals, but inoculation of guinea-pigs with the *Coccidioides* organism tends to cause caseous degeneration of the testicles, a fact never observed in the case of the *Blastomyces*. The fungus of *Blastomyces* multiplies by budding; that of *Coccidioides* does not, the sole mode of reproduction of the latter being by means of an endogenous spore formation. Additional characteristic points of *Coccidioides* as against *Blastomyces* are that the capsulated bodies in the tissues are comparatively large and usually circular; the infection tends to become generalized; the prognosis is bad; the administration of iodide of potassium has no control over the disease.

Eczematoid Eruption of the Lip.—A peculiar eruption about the region of the lips is described by H. W. STELWAGON (*Jour. Cut. Dis.*, August, 1904) as usually beginning on the vermilion border of the lips, showing at first a superficial eczematous condition, with scanty expoliation, no liquid exudate has been seen, burning and heat may be complained of, but seldom any troublesome itching. This condition tends to retrogress sooner or later to present again. After some weeks or months the disease extends to the skin, frequently at the same time spreading inward over the mucous membrane. The upper lip is always much less affected than the lower; in some instances the tongue has become likewise affected. Contiguous to the affected area on the lip or slightly beyond, one or more small reddish, flattened or rounded persistent lesions appear, which later exhibit scaling, sometimes crusting, but no exudation. The disease is of a benign character, never showing any destructive action. Anti-syphilitic treatment tends to aggravate rather than improve the condition. The most satisfactory treatment of the cutaneous lesion is sulphur 20-60 gr. to the ounce of Lassar's paste, or painting with 10-50 per cent. alcoholic solution of resorcin.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Peritonitis after Phlegmon of Arm.—That peritonitis may develop through a retrograde transport of germs from the arm by way of the lymphatic system is clear from the two cases published by M. LOHLEIN (*Virchow's Archiv*, Vol. 177, No. 2). Streptococci had gained access to the subcutaneous cellular tissue of the left arm, and had then traveled to the gland of the axilla. From here the upper end of the thoracic duct was invaded and the opening into the subclavian vein obstructed by a thrombus, so that the germs found a ready opportunity to travel backward into the peritoneum. Both patients had developed indefinite pains in the abdomen a short time after their injury, and soon the typical picture of peritonitis appeared. Septic infection of the thoracic duct is more common with infection of the uterus, but here the germs travel with the lymph-stream, not against it.

Recent Investigations in Hay Fever.—A discussion of recent experimental work on hay fever is made by R. A. GLEGG (*Jour. of Hyg.*, July 9, 1904). The researches were conducted by Prof. Dunbar, which show that there is in reality but one exciting cause for hay fever, this being the pollen of grasses and of certain other plants. He found that these pollens could artificially excite attacks of hay fever when applied to the conjunctivæ or nasal mucous membranes of persons predisposed to the disease, and this even outside of the hay-fever period. Dunbar succeeded in isolating the peculiar poison in the toxic pollen, and found it to be an albuminous substance, so toxic that even .000025 milligrams of the proteid body, consisting of this active albumin and also of inert globulin, could excite irritation in the conjunctiva of a predisposed patient. This amount of toxin would be contained in two or three pollen grains. Large doses produced very severe attacks, and toxin injected subcutaneously produced most unpleasant, and indeed dangerous, symptoms in two hay-fever patients. This toxin is absolutely without any effect on normal persons. By injecting pollen toxin into animals Dunbar succeeded in obtaining an antitoxin, which neutralized the toxin in vitro and cut short attacks of hay fever artificially produced by the toxin. Furthermore, the antitoxin cut short attacks of the natural disease. Owing to the peculiar nature of the disease and the constant reinfection of the mucous membranes by pollen on exposure to the outside air, Dunbar has found it to be necessary to use the serum prophylactically, to sleep with the windows closed, apply serum in the morning before rising, both to eyes and nose, and again during the day on the appearnce of the slightest irritation in the conjunctiva or nasal mucous membrane. By this means he has succeeded, and others have also been successful, in acquiring freedom from attacks.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

EDDYISM AND MAGNETIC HEALING.

THE recent exposé of Eddyism, showing that it had its origin not even in a supposedly divine revelation, but developed in a very matter of fact manner from a system of magnetic healing invented by one Dr. Quimby, of Maine, should receive more than passing attention from physicians. We are indebted to the enterprise of the New York *Times* for putting into popular language with further evidence the extensive study of Woodbridge Riley in the "Personal Sources of Christian Science," *Psychological Review*, November, 1903.

According to this well-authenticated story, it is easy to trace the gradual evolution of an ordinary magnetomental system of therapeutics into modern Christian Science, with its presumptuous claim to definite divine revelation. The investigation also throws no little light on the career of Mrs. Eddy herself. According to her disciples, in 1866 she fell on an icy sidewalk and hurt herself. The official Eddy version is that this led to the discovery of Christian Science. Her Bible opened to the account of the healing of the palsied man. She immediately saw the truth, and recovered without the aid of medicine. The physician who attended her, Dr. A. M. Cushing, now of Springfield, Mass., gives a different version. He says he found her nervous, semi-hysterical, and considered it necessary to give her quieting medicine rather frequently. At subsequent visits she complained so much of discomfort that he found it necessary to give her morphine. During her visits to him she occasionally spoke of Dr. Quimby, of Portland, Maine, and stated that he had wonderful success in treating her.

Documents are furnished in the late exposure which show that many of Mrs. Eddy's expressions with regard to science and health are copied directly from the pamphlet of Dr. Quimby. Some of this author's manuscripts are shown in facsimile with corrections and interlineations in Mrs. Eddy's own handwriting, which serve to bring out very clearly certain steps in the evolution of Quimby's magnetic healing into Eddyistic Christian Science. At first, indeed, Mrs. Eddy, according to competent witnesses still alive, gave due credit to Dr. Quimby. Only later, when success began to come to her, when she realized the possibilities of such a declaration, did she insist that her new doctrines were a direct personal revelation to her from on high.

This claim becomes doubly absurd in the light of the disclosures. Its refutation is written by Mrs. Eddy herself. Such familiar Eddyistic expressions as "The patient's disease is in his belief," "Error is sickness, truth is health," are directly traceable to Dr. Quimby's writings. With very slight modifications they are to be found even in recent editions of Mrs. Eddy's book. Occasionally there are modifications such as "Error is matter" (Quimby), "Matter is mortal error" (Eddy), "Matter has no intelligence" (Quimby), "The fundamental error of mortal man is the belief that matter is intelligent" (Eddy). As Riley puts it, however, "it is needless to go into the muddy question of plagiarism. There is no real issue between the Eddyite and the Quimbyite, because the head of each school drew their philosophic trickle from a common source. One of the chief ex-Christian Scientists himself grants that there was a near approach to the theory and practice of Dr. Quimby in the contemporary investigation of John Bovee Dods, who believed that electricity was the connecting link between mind and matter, that disease originated in the electricity of the nerves and can be cured by a change of mind." "It was from the vaporings of itinerant magnetizers that Mrs. Eddy sucked in her primary notions." "The quacks were drawing full houses in New England at

the very time she was on her pilgrimage for health." Hence the true history of "Mental Science" is to be traced, not to the original Quimby, but to the indiscriminate practice of mesmerism along in the forties and fifties, and to the crude attempts of Yankee philosophers to explain the borderland phenomena of hypnoidal states.

ATHLETICS AND ARTERIOSCLEROSIS.

We are just entering upon the period of the year when, with the opening of the universities, a very large number of young men in this country settle down to the hardest kind of athletic training for the various sports. It seems not inopportune then to review for a moment certain recent expressions of medical opinion with regard to the immediate and remote effects of the severer forms of athletics upon the general health, exercise, and especially those sequelæ that may influence length of life. Not a few of those who took part in the very interesting discussion on arteriosclerosis at the last meeting of the American Medical Association insisted on the fact that the violent forms of athletic exercises most in vogue at universities at the present time are likely to be sources of early arterial degeneration with consequent early loss of vigor and curtailment of life.

As far back almost as medical history runs, it has been conceded that the most harmful factor in breaking down health and in shortening life was severe labor during the period of adolesence and bodily development. This would include especially the years between fifteen and twenty-three, when, after puberty, the body is gradually reaching its acme of development. It is considered almost a truism to say that strenuous physical labor at this time, if carried on to the fullest limit of capacity, is sure to lower resistive vitality and hinder proper development. There are not many who would hesitate to say that to compel growing boys between fifteen and twenty to strain themselves lifting heavy weights, which they are just able to carry, or to work so hard that they sometimes faint because their hearts refuse to send a sufficient amount of blood to the brain, is actually criminal. In what the compulsion to labor so hard differs from athletic exercises which call for just as much exertion and produce as serious effects upon the individual is hard to understand. It is this point particularly that a number of good clinical authorities at Atlantic City insisted on, and suggested that the faculties of our universities should be made to realize.

"A man is as old as his arteries" is a popular truism that remains quite as true for the physician as for the general public. The etiology of premature degeneration of arteries is well-summed up in the expression of the distinguished American clinician who says that it occurs especially in the devotees of the three pagan deities, Vulcan, Venus and Bacchus, that is, it occurs in those who work too hard, in those who suffer from venereal disease rather than from excesses in venery, and in those who indulge too much in spirituous liquors. The relative etiological importance of the causative agents at work is expressed by the order in which they are mentioned above.

There is no single factor in the production of precocious senility due to degeneration of arteries so effective as hard physical labor. The series of statistics presented at the recent meeting of the American Medical Association with regard to the development of arteriosclerosis under forty-five years of age brought out this fact very forcibly. It is no wonder then that there should be agreement among physicians as to the utter inadvisability and almost inevitable harmfulness of the severe physical strain of certain phases of modern athletics.

There is another important element also likely to be harmful in its tendency to which attention was not directly called, although certain of those who took part in the discussion did insist on the necessity for careful dieting and especially on the avoidance of excesses in animal foods, if arteries are to be kept in their normal elastic condition. There is no doubt that an excessive nitrogenous diet adds its quota of irritation to nerves and arteries and leads to unfortunate consequences. The strain put upon the kidneys by such a form of diet is much more severe than with the ordinary mixed diet containing a larger proportion of carbohydrates, which is so much more suitable for the adolescent period. There are forms of heart and kidney disease that consequently develop in association with arterial degeneration, and it has never as yet been decided just in which set of organs the pathological condition is primary.

There would seem to be no doubt then that those who apparently are in the best position to judge are agreed that our modern athletics are sure to do much harm unless more carefully regulated. Under these circumstances it might be expected that university faculties would take cognizance of these conclusions and insist on limitation of present day customs with regard to the

severe forms of athleics and the training for them.

THE MENINGES IN THE ACUTE INFECTIONS OF THE RESPIRATORY SYSTEM IN CHILDREN.

DURING the progress of pneumonia or bronchopneumonia children frequently suffer from generalized convulsions. These convulsions may often be mistaken for meningitis, and they enter into the picture described by Dupré under the name of meningism, which this authority attributed to a true meningeal reaction without any anatomic lesions.

The clinical and experimental researches of Dr. Roger Voisin, presented in his recent thesis (Paris, 1904), throw a new light on the obscure question of meningism. Clinically, all degrees of meningeal phenomena of bronchopneumonia are met with, such as convulsions, stiffness of the neck, Kernig's sign, even the classical picture of acute meningitis—nothing is wanting.

This variability of the clinical signs is also met with in the conditions presented by the cerebrospinal liquid. Obtained by lumbar puncture the cerebrospinal fluid shows a normal condition, or, on the other hand, there may be slight changes of the albumin, or the amount of sodium chloride present, while in some cases it is purulent.

The meninges themselves present divers lesions, and every condition may be observed from the normal state to congestion, serious edema, or even the inflammatory changes of acute meningitis. One might be led to believe that with these lesions of meningitis and purulent condition of the spinal fluid that a patient would present a complete clinical picture of meningitis with violent convulsions, etc. But this is not the case, because a slight lesion may give rise to an imposing array of head symptoms while, on the other hand, a child with bronchopneumonia may die and the autopsy will show advanced lesions of meningitis, although no symptoms of the affection manifested itself during life.

The pyramidal cell of the cortex consequently presents a peculiar and different reaction according to the case. The variability of the clinical picture is only the expression of the special susceptibility of the hereditary or morbid origin of the nervous centers. They react against the blood infection in bronchopneumonia or the intoxication as Voisin has demonstrated experimentally. All degrees of infection or intoxication of the nervous centers are met with in bronchopneumonia, just as one sees all the various degrees of renal lesions in pneumonia.

The alcoholic subject reacts against the alcoholic intoxication by his liver, kidneys, stomach or brain; in other words, the organs which by heredity is the weak point. It is the same with bronchopneumonia, and the apparition of the meningeal syndrome is favored by nervous heredity.

The prognosis varies according to the anatomic type, but should the meningeal symptoms persist in spite of tepid baths, and if the restlessness is not interrupted by periods of calm with sleep, one should be on guard, because a serious meningeal lesion may be developing.

ECHOES AND NEWS.

NEW YORK.

Bequest to Eye and Ear Hospital.—Dr. William H. Crawford, who died August 28, at 205 West Fifty-seventh Street, left $10,000 to the New Amsterdam Eye and Ear Hospital.

Health Department Funds.—The Health Department has sent to the Board of Estimate its estimate for 1905. According to the figures, the department will need $2,123,500, as against $1,109,391.48 allowed for this year. When the allowances by bond issues and other income are deducted the increase asked is reduced to $577,636.52. The estimate says the increase is due mainly to the hospital fund and salaries increase.

New Hospital for Brooklyn.—For the purpose of instituting and maintaining a charitable hospital in the neighborhood of Fifteenth Street and Fourth Avenue, Brooklyn, the Brooklyn Samaritan Hospital Association has been organized. It will be incorporated, and the work of raising funds will be begun soon. This movement is the outcome of the dispensary work that has been carried on under the auspices of the Fifteenth Street Baptist Church. The proposed institution, however, will be non-sectarian, patterned somewhat after the Samaritan Hospital, in Philadelphia.

Diphtheria in the Bronx.—Diphtheria has been prevalent in West Chester and Throgg's Neck for the last week, and has given the health officials much worry in view of the opening of the public schools. Most of the physicians in the neighborhood of West Chester have had cases and a strenuous effort is being made by the local superintendent of the department to stamp out the disease.

Interpreter for Bellevue.—Ermenegeldo Zordan, a Professor in the University of Padua, who speaks English, German, Italian, Spanish, Polish, Yiddish, and modern Greek as well as he does French, his native tongue, has been appointed official interpreter at Bellevue Hospital, an office that the institution has needed for many years. Professor Zordan, who is on a two years' leave absence from the University of Padua, Superintendent Richard says, is without doubt one of the most talented linguists who ever came to America.

Smallpox on Steamship.—The steamer Campania was held at quarantine several hours because of a case of smallpox on board. The victim, a woman steerage passenger, was transferred to a shore hospital, and twenty-five of the steerage passengers were sent to Hoffman Island for observation. The steamer was released after she had been disinfected by the health authorities.

Analysis of Foodstuffs in New York.—Under the direction of the Department of Agriculture, a chemical

laboratory for the analysis of imported food products has been opened in the Appraiser's Stores building in Greenwich Street, in this city. All necessary apparatus to detect impurities was installed on the tenth floor of the building during the day, and hereafter importers will not be subjected to the delay of having samples sent to Washington for analysis before they can obtain their goods. This laboratory will be the third of its kind in the United States, as there is already one in San Francisco, besides the Department headquarters in Washington. Dr. H. W. Wiley, chief of the Bureau of Chemistry of the department, was in this city to superintend the installation. L. M. Tolman had also come from Washington for the preliminary work. R. E. Doolittle, formerly State Chemist of Michigan, will have charge of the work here, and will be assisted by Alfred W. Ogden and B. R. White.

PHILADELPHIA.

Typhoid Again Increasing.—Typhoid fever cases for August numbered 454 as against 257 in July. The present increase is attributed largely to a broken sewer which discharged for nearly a week into the Schuylkill a short distance above a pumping station.

Mont Alto Sanatorium.—Encouraging reports come from White Pine Camp Sanatorium, near Mont Alto, established by the State for the treatment of consumptives. All the patients in camp are said to be improving and a number have been completely cured. A large area of ground has been laid out in garden plots and in caring for these the patients take their prescribed exercise.

Serum Treatment for Tuberculosis.—A consignment of the Maragliano serum for use in combatting tuberculosis has arrived from Europe and is to be employed by the Phipps Institute. Directions for its use have been sent by Drs. Ravenel and Pearson who have been investigating its properties during the past summer.

Basis of the Weightman Fortune.—The recent death of William Weightman, head of the firm of Powers & Weightman, drug manufacturers, has again revived the story of how a large part of the immense fortune of the firm was derived from the sale of quinine during the Civil War. At that time there were only two concerns in this country making quinine from Peruvian bark—Powers & Weightman and Rosengarten & Sons, both Philadelphia firms. The regular price of the drug at the beginning of the war was $2.10 per ounce. Heavy war duties as well as the general effect of the war sent the price up and the two firms made money rapidly, although the government purchased great quantities of the drug abroad. Neither firm sold quinine directly to the Confederates, though it reached them by way of traders who ostensibly bought it for other uses. These men also reaped a rich profit, for the drug south of Mason and Dixon's line often sold for as high as $15 an ounce; the Philadelphia firms, though having a monopoly of the product, never sold it for exorbitant prices.

The Copper Treatment of Drinking Water.—Interest in this subject still runs high in this city, no doubt because of the condition of the water supply and the imminence of another typhoid outbreak. The Philadelphia *Ledger* of Monday prints a two-column interview with Dr. George T. Moore, in charge of the laboratory of plant physiology in the Department of Agriculture, Washington. In the course of the interview Dr. Moore made this statement: "I am perfectly willing that the *Public Ledger* should say for me, since it asks for a broad, free, unqualified statement, that the death rate in Philadelphia or any other community, from typhoid fever, so far as the disease is caused by infected drinking water, may be wiped out by the scientific use of copper as a germicide." The laboratory experiments in this city, inspired by the announcement of Dr. Moore some time since, are stated by Director Martin as not ready for publication. His statements, as recently published, were rebutted by several well-known chemists of the city and in endeavoring to sift the matter the *Ledger* obtained the interview now made public. Dr. Moore's statements more than confirm those of Dr. Martin, although no official correspondence has passed between the two. The findings of the Agricultural Department grew out of experiments made to destroy algae in reservoirs of drinking water. The germicidal properties of copper as announced are based on laboratory experiments as no public water supply has been treated for bacterial contamination. This is beyond the pale of its duties. Moore considers the popular prejudice against copper vessels because of fear of poisoning as absolutely unwarranted; he was surprised by the adverse opinions of the Philadelphia chemists who opposed the views of Dr. Martin. He explains them only by the supposition that they are chemists only and not bacteriologists, biologists, physiologists or students of pathogenic growths. What is popularly called verdigris is carbonate of copper formed by the action of carbonic acid on the metal and is, for all the purposes of popular argument, not soluble in water. Verdigris proper is an acetate or acid product and would not form under such conditions. Further experiments are to be conducted by the Department, and it is not unlikely that they may look to the practical application of the treatment to large bodies of water.

CHICAGO.

Hospital for Oak Park.—Fifty Oak Park residents, among them a number of physicians, recently met and discussed plans for a proposed hospital. All agreed to support the project. After several speeches a committee of ten was appointed to arrange for a larger meeting to further the plan.

Opening Exercises of Dearborn Medical College.—The Dearborn Medical College opened its new home at Michigan Avenue and Twelfth Street in the building formerly occupied by the Chicago Manual Training School, August 30. The assembly hall was decorated with flags, ferns and flowers, and was filled with students and friends. Dr. L. Blake Baldwin, president of the college, introduced Dr. George F. Butler, superintendent of the Alma Springs (Mich.) Sanitarium, and Dr. Homer M. Thomas, of Chicago, who delivered addresses. The faculty has expended $10,000 in remodeling and furnishing the building, and the school begins with an enrollment of two hundred students. This is the second year of this night medical college, which began last season in the Illinois Pharmacy Building with 135 students.

New Hospital for Englewood.—The Swedish-American Hospital Association of Englewood was recently given a charter at Springfield. Capital stock is $100,000, all of which must be subscribed before work on the building is begun. The hospital will be in Englewood, but the site has not been chosen.

State of Chicago's Health.—The *Bulletin* of the Health Department for the week ended August 27, contains the following gratifying report: "If that nation is to be accounted happy that has no history, why not the city whose healthfulness furnishes little or nothing of the material of which history is mostly made—death, disease and disaster, pestilence, plague and woes unnumbered? With two-thirds the usually sickly summer season already passed, the August death rate is as low as the rates of the healthful June and November, the

two months of least mortality in the twelve. Even with an increase of thirty-five more deaths reported over the number of the previous week the total 472 is 114 less than for the corresponding week of last year and the rate per 1,000 of population is more than 16 per cent. lower than the rate of that week. One of the most gratifying features, next to the continued low mortality among infants and children, is the infrequency of typhoid fever. This disease always shows a seasonal increase, beginning in July and culminating in October. The increase has averaged for thirty years more than 63 per cent. in August over the rate of the first six months of the year, which would make the typhoid deaths for this month about 47. During the last twenty-seven days there have been but 26 deaths from typhoid fever reported and a total for the month is not likely to be more than 31 or 32. In August, 1903, there were 51 deaths from typhoid fever. A similar, but not so marked, reduction in the acute intestinal diseases—also due largely to impure water—is noted. Thus far during the month there have been 441 deaths due to this class of diseases. In the corresponding period of last year there were 505 such deaths; during the week there were 102 acute intestinal disease deaths and one year ago there were 142. Cool weather, pure water and the improved quality of milk supply are the principal factors producing these results."

Fourth-of-July Lockjaw Record.—Anent an interesting article, which appears in the *Journal of the American Medical Association,* under date of September 3, the *Chicago Record-Herald* of same date contained the following editorial on "Fourth-of-July Tetanus": "If the use of pistols, cannon crackers, cannon and cartridge canes had been prohibited on the Fourth of July there would have been only one death from Fourth-of-July tetanus in the entire country this year. This statement is made on the authority of *The Journal of the American Medical Association,* which for two years has collected Fourth-of-July accident statistics in the most complete possible manner. As it was, 105 cases of tetanus were reported, in 91 of which death is known to have resulted. In 74 of these cases blank cartridges caused the injuries. The record, bad as it is, is nevertheless gratifying in comparison with that a year ago, when 415 tetanus cases resulted from the glorious celebration, among which were only seven known recoveries. *The Journal* finds that tetanus due to other causes than Fourth of July injuries is, if anything, more than usually common this summer. It also believes that last year's record of Fourth-of-July deaths was not above average for recent years. It therefore feels justified in inferring that the campaign against the lockjaw Fourth in the public and professional press, taken in connection with the stricter legislation and the more careful medical treatment of accidents which have been brought about by it, is responsible for the greatly improved showing of this year's celebration. It urges that the efforts for a sane Fourth which have been thus far made should be continued with even greater vigor until our national holiday will become again a pride, instead of a cause of disgrace, to the country. In Chicago, where the death list was reduced from the sixteen of 1903 to five, further action should clearly be taken. The first thing to be done is for the council to pass an ordinance prohibiting absolutely the sale of toy pistols and similar death machines, instead of merely prohibiting their sale to minors as at present. Beyond that, however, agitation should be begun for the passage by the state general assembly of a law prohibiting the manufacture of such articles. When the toy pistol, cannon cracker and the cartridge-cane are driven out of existence, plenty of varieties of fireworks will still remain to give old and young all the noise and all the entertainment they can need on the year's day of greatest enthusiasm."

GENERAL

Arrival of Professor Orth.—Dr. J. Orth, professor of pathology and dean of the University of Berlin, arrived on the Zeeland Sept. 5, accompanied by his wife. Professor Orth, on the death of Professor Virchow, was called by the faculty of the University of Berlin from Göttingen to fill the vacancy. Professor Orth was, early in his career, one of Virchow's assistants. He was the chief physician in the operation recently performed on Emperor William's throat. Many of his pupils are now prominent American physicians. The professor will go to Albany, Buffalo, Niagara Falls, Chicago and St. Louis. He will be entertained at the White House by President Roosevelt on September 27, and dinners will be given for him in Baltimore by educators of Johns Hopkins and by a body of his former pupils, now in America.

Smallpox in Connecticut.—The second outbreak of smallpox in South Manchester within the last two years was discovered September 2, when three in one family were stricken.

Tuberculosis Sanitarium at St. Louis.—East St. Louis is to have a $100,000 sanitarium for the cure of consumptives. A tract has been purchased as the site for the new enterprise. The company will be capitalized at $200,000. Plans for the buildings are being drawn, and it is intended that the sanitarium shall be open to patients early in the spring.

Hay-fever Epidemic.—An extraordinary epidemic of hay-fever has developed in Buffalo and vicinity within the past two or three days. Several thousands of Buffalonians are sneezing, choking, and suffering from this enervating ailment; the attack was as sudden as it is sweeping.

Panama Sanitation.—A long step toward the sanitation of the Isthmus of Panama will be accomplished within six months by the installation of a complete system of waterworks for the city of Panama. The reservoir from which the city water supply will come is partly completed, a dam constructed along the line of the canal by the French company being utilized, and the lake formed thereby will contain a supply of pure water sufficient to furnish each inhabitant of the city with fifty gallons daily for five months, even if no rain falls in that period.

Sanitary Work at Canal Zone.—The sanitary officials at the canal zone have reported that quarantine stations have been placed at both ends of the canal route to prevent the spread of yellow fever and the plague, the latter generally coming from Chili and Peru. The most active methods for preventing the plague from breaking out are being employed. The methods are the same that are used in Havana. Sewers are being built and all water is being covered up as much as possible. Plumbing is being introduced, and a campaign is being conducted to teach the people to better their conditions. A large force of men is employed killing the mosquitoes, and gangs are filling up the swamps to keep the pests out of the country. To keep out the plague, an eight-day quarantine to vessels from infected ports has been established.

Sanatoria for Tuberculous Poor in England.—The great friendly societies of England, the trades unions and other organizations of workers, have formed a national committee which has for its purpose the establishing of sanatoria for workers. The municipalities are also being urged to provide beds for all persons of the working classes who need to be cared for, and it is estimated that an annual expenditure of $5,000,000

would be quite sufficient for the isolation of all tuberculous patients. As one-eleventh of the total expenditure of $60,000,000 annually for the public care of the poor of Great Britain is thought to be due to pauperism caused by this disease, the expenditure of this sum would not seem to be unreasonable if, by this means, the disease could be stamped out.

Society to Study Alcohol and Narcotics.—The American Society for the Study of Alcohol and Narcotics was formed last June by an amalgamation of the American Association for the Study of Inebriety and the Medical Temperance Association. Its plan of work is to encourage and promote more exact scientific studies of the nature and effects of alcohol in health and disease, particularly of its etiological, physiological, and therapeutic relations. Second, to secure more accurate investigations of the diseases associated or following from the use of alcohol and narcotics. Third, to correct the present empirical treatment of these diseases by secret drugs and so-called specifics, and to secure legislation prohibiting the sale of nostrums claiming to be absolute cures containing dangerous poisons. Fourth, to encourage special legislation for the care, control, and medical treatment of spirit and drug takers.

Radio-active Wool.—A new method of employing radium in medicine has been described by E. S. London, a Russian physician, which consists of using cotton-wool which has been submitted to the action of radium emanation. The result of a series of experiments seems to justify the conclusion that the effects of the radium emanation and of the direct action of the radium are the same, consisting in an inflammation of the skin and a destruction of protoplasm. Wool so treated, which is convenient for easy distribution over the body, when packed in hermetically sealed jars or other containing vessels, loses its radioactivity very slowly, and can be sent to any distance desired. From a few milligrams of radium a large quantity of wool may be prepared, and thus widely extend the use of a small amount of radium, whose cost is so great as to interfere with its widespread use. Radio-active wool, therefore, may become a stock pharmaceutical preparation, but it still remains for the medical profession to determine its therapeutic value.

Breathing in High Altitudes.—The difficulties of respiration at high altitudes has been believed to be due to the reduced tension of the atmospheric oxygen. Professor Mosso, an Italian scientist, has recently disproved this theory by showing that if the pressure of the mixture of oxygen and nitrogen making up ordinary air be reduced to one-third of an atmosphere, and then the proportion of oxygen be increased so that its partial pressure is the same as normal, the mixture is breathed with inconvenience, accompanied by an abnormal respiration and pulse. By taking supplies of pure oxygen and mixtures of gases to the summit of Monte Rosa and analyzing the blood it was shown, however, that a diminution in the amount of carbon dioxide in the air due to the low pressure was doubtless responsible for much of the trouble in respiration. Proof of this was afforded by breathing a mixture of 80 per cent. of oxygen and 20 per cent. of carbon dioxide on top of Monte Rosa, with a feeling of pleasure and ease, while the effect of the same mixture near the sea-level in Turin was to produce giddiness and vomiting. If this discovery is substantiated by further experiments it seems that by carrying cylinders containing this mixture of gases the highest mountain peaks can be scaled, while the mere provision of oxygen is of doubtful utility.

Alcoholism in German Schools.—An interesting investigation on the prevalence of alcoholism among school children in Germany has recently been published. Its author, Dr. Goldfeld, believes that the situation is serious, and should be brought to the attention of the parents by means of addresses at meetings and by the distribution of essays on the evil effects of alcohol. The investigator is medical officer of the public schools of Schöneberg, a suburb of Berlin, and his examination included 967 children, 470 of whom were in a boys' school and 497 in a girls' school. Of these, 496, or 51.3 per cent., were accustomed to drink from one to two glasses of beer daily, while 299, or 30.9 per cent., took spirits more or less frequently. The favorite beverage was malt beer, but all kinds of beer and various kinds of spirits were taken, the sweeter liquors being preferred by the girls. Dr. Goldfeld was informed by the teachers that the children addicted to the use of spirits were especially lazy, absent-minded, and inclined to lying. Neither children nor parents heeded Dr. Goldfeld's warning. Of the 470 boys mentioned, 264, or 56.2 per cent., drank beer daily, and 139 were casual drinkers. One class was found in the school where practically the entire membership (96.2 per cent.) were accustomed to use alcohol in some form or other, while in another class there was only a third. The consumption of spirits by different classes varied from 17.7 to 60.4 per cent. With the girls the figures ranged somewhat lower, but still they are considered serious, and from the data presented there apparently is good opportunity for a scientific temperance propoganda in the German schools.

OBITUARY.

Dr. E. G. Simons, of Ripley, N. Y., was instantly killed by a Lake Shore freight train in Glenville, Ohio, on September 1.

Dr. William Hammet Martin, sixty-four years old, died at his home, No. 221 West 135th Street, New York city, on September 3 after an illness lasting several weeks, from cancer of the stomach. Born in Louisville, Ky., later a graduate of Columbia University and the College of Physicians and Surgeons, Dr. Martin for some years practised in Madison, N. J., and afterward in this city.

Dr. Millard Fillmore Cyphers, died at his home on Woodland Avenue, Philadelphia, August 29, aged forty-five years. He was born in Wilkesbarre, and after graduating at the University of Pennsylvania in 1887, practised for some years in his native city before coming to Philadelphia.

Dr. Henry Tuck, vice-president of the New York Life Insurance Company, died September 2 at Seabright, N. J., after a long illness. Dr. Tuck was born in Barnstable, Mass., in May, 1842. After a preparatory training at the Boston Public Latin School he entered Harvard College, from which he was graduated in 1863. Soon after leaving Harvard, Dr. Tuck took a course in medicine at the Harvard Medical School and received his degree in 1867. He took part in the last campaign of the Civil War. He was appointed acting assistant surgeon in the army and was present at Lee's surrender at Appomattox. Later he went abroad to complete his study of medicine, the greater part of his time being spent in Vienna, where he studied at the General Hospital. Returning to this country in the latter part of 1868, he established a large and lucrative practice in Boston. After nine years in that city, in which time he acted as medical examiner for the Mutual Life and several other insurance companies, Dr. Tuck came to this city. In November, 1877, he was elected medical director of the New York Life Insurance Company. He became a trustee of the company in 1878, senior medical director in 1883, second vice-president in the same year, and senior vice-president on the election of Mr. Beers to the presidency in 1885. For twenty-seven years

Dr. Tuck had been a directing force at the home office, and in the board of trustees and as an executive officer he had given to the company the best service of a trained mind, a large experience and a whole-hearted devotion to its highest interests. Dr. Tuck was twice married. His first wife, whom he married in 1873, was Miss Emma R. Beers. After her death and in September of last year, he married Eleonore Hammond. While in Boston Dr. Tuck became a member of the principal medical societies of that city, and was one of the physicians of the Massachusetts General Hospital. He was a member of the University and Reform clubs, the Society of Mayflower Descendants and the New York Academy of Medicine.

DR. JOHN L. GORMLY, one of the rising young physicians in Brooklyn, died September 6, of heart trouble, at his home, Ocean Parkway and Avenue D, Brooklyn, N. Y. He was twenty-nine years old. He was on the visiting staff of St. Mary's Hospital.

SPECIAL ARTICLE.

EXCURSIONS IN OLD NEW YORK MEDICINE.—V.

DR. DAVID HOSACK AND HIS BOTANICAL GARDEN.

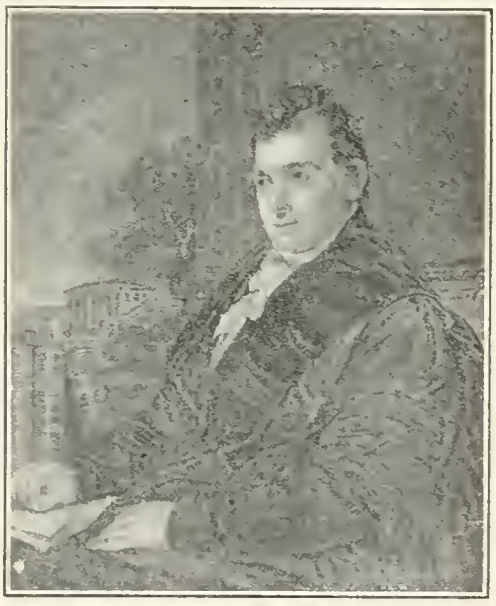
DURING the present year the newspapers have frequently called attention to the fact that the property owned by Columbia University in the heart of the city (Fifth Avenue and larger Forties) is a legacy from the State to the institution, of Dr. David Hosack's Botanical Garden. To most New York physicians the name of Hosack is familiar because the main meeting hall at the Academy of Medicine is called after him. This distinction is due, partly at least, to a bequest to the Academy on the part of his widow. Dr. Hosack deserves, however, to be a familiar character to members of the medical profession in New York City and State for many other and better reasons than even his botanical garden or the family interest in the Academy of Medicine. There is perhaps no one person in the nineteenth century to whom New York medicine is more deeply or widely indebted than to this learned, faithful, generous, liberal man, of whom it might well be said, in the words of the old Roman dramatist, that "nothing that was human was foreign to him."

Dr. Hosack is one of the physicians, not many in number altogether, who have deservedly found a place in the volume, "Pioneers of Science in America,"[1] which was a reprint of the sketches of the lives and scientific work of the most prominent American scientists, edited and revised by the late Dr. William Jay Youmans, who had been for many years the editor of the *Popular Science Monthly*, in which the sketches originally appeared. The first paragraph in the sketch, written by Dr. Youmans, gives an excellent idea of Dr. Hosack's prominence as a man as well as a physician in New York City life:

"In the early part of the nineteenth century no citizen of New York was held in higher honor than was De Witt Clinton. Closely associated with Clinton in the leadership of the civic life of the day, but holding rigidly aloof from politics, was Dr. Hosack. 'It was not infrequently remarked by our citizens,' said his pupil and associate, John W. Francis, 'that Clinton, Hosack and Hobart were the tripod on which our city stood.' Dr. Hosack was one of the founders of the New York Historical Society and its president from 1820 to 1828. He was also instrumental in founding an art society, was prominent in various scientific, literary and humane undertakings, and, if his lead had been followed, New York would have to-day a botanic garden equal to any in a European metropolis."

When Dr. Youmans wrote this, New York was without a botanical garden. Since then, thanks to the inspiring influence of Hosack's early work, this municipal defect has been made good, and we now have what even Dr. Hosack's biographers would pronounce "a botanic garden equal to any in a European metropolis," and we may even add, without undue conceit, far better than the great majority of the older cities may ever hope to have, since the energetic work of Dr. N. L. Britton is now bearing fruit.

Meantime we must not be blind to the wonderful pioneer work accomplished nearly a century ago. How extensive was Dr. Hosack's work and how ambitious his aim in having the botanical garden as complete as possible may be gathered from a paragraph from his son's biography. Hosack's idea was to make it an institution similar to the Jardin des Plantes in Paris. He meant to include all the features of that institution, even the zoological and mineralogical collections. In a word, a hundred years ago he conceived the idea of giving New York a botanical garden and zoological garden besides a museum of natural history.



DR. DAVID HOSACK.

His son says: "At this time there were under cultivation nearly fifteen hundred species of American plants, besides a considerable number of rare and valuable exotics. To this collection additions were made from time to time from various parts of Europe, as well as from the East and West Indies. It was the intention of the founder of this beautiful garden, had his means been more ample, to devote it to the sciences generally, more especially those of zoology and mineralogy. This, however, he was compelled, from want of fortune, to relinquish, hoping that the State of New York would at some future day be induced to carry out the plan, as suggested by him, similar in all respects to that of the Garden of Plants in Paris; but in this he was disappointed. The State purchased the garden from him, but, like many other public works unconnected with politics, it was suffered to go to ruin. While it was in his possession it afforded him many a pleasant hour of

1 New York: D. Appleton & Company, 1896.

recreation, and served to abstract him from the cares and anxieties of an arduous profession. Frederick Pursh, author of the *Flora Septentrionalis*, was for several years curator of this garden."

In the midst of his scientific work, however, Hosack did not forget his duties toward his fellowmen, but, on the contrary, was constantly occupied with humanitarian progress. A society which had existed in New York up to his time for the purpose of visiting prisoners in jail, in order to be of help to them, if possible, and which actually accomplished the great good of supplying prisoners for debt with provisions, was developed under the stimulus of Hosack's enthusiasm into the Humane Society, whose aim was not only the relief of prisoners, but also of the poor in order to prevent the commission of crime, if possible, and even included some safeguard for animals against heartless cruelty. The City Dispensary, for the care and treatment of the ailing poor, received unstintingly of his time and attention. It was he who first advocated the necessity for a separate hospital building for contagious diseases. More than any other he contributed to the spread of popular knowledge with regard to the necessity for quarantine, and so made its institution practicable. Public sanitation was always a matter of deep interest to him, and it was he who first urged that the city's sewers should be made to discharge at the outer piers instead of the bulkhead line.

Notwithstanding his devotion to so many interests that must have made very serious demands upon his time, Dr. Hosack somehow found opportunity to make a large number of contributions to medical literature. When quite a young man he began the publication of *The Medical and Philosophical Register*, the quarterly journal, in the publication of which Dr. John W. Francis was associated with him. Later in life he published three volumes of medical essays containing articles contributed to various journals, occasional addresses before scientific bodies and medical societies, introductory lectures to his regular medical courses the College of Physicians and Surgeons, and the like. He edited an English work on the practice of medicine that had been written by Dr. Thomas, of Salisbury, England, and added an extensive appendix, making the work more practically useful for American physicians. Later on he also published a text-book on medicine of his own, which ran through several editions.

DR. HOSACK'S MEDICAL STUDIES.

In Dr. Hosack's career there are traces of the existence of a custom with regard to education which unfortunately does not continue to the present time, though it still obtains, to some extent at least, at the German universities. Instead of spending his senior year at Columbia, he spent it at Princeton. His idea was to have the advantage of being brought intimately in contact with certain scholarly professors at the college of New Jersey, whose work had attracted his attention. As he says himself:

"My great inducement for removing to Princeton was my desire to complete my course of collegiate studies as soon as possible, in order to devote my exclusive attention to medicine, to which I had now become ardently attached, and that I might also have the benefit of attending the valuable lectures on Moral Philosophy and Elocution delivered by the learned president of that college, the Rev. Dr. Witherspoon; those of Belles-Lettres and Composition, by the vice-president, the Rev. Dr. Samuel Stanhope Smith, and the instruction in mathematics and natural philoshophy, by the celebrated mathematician, Dr. Walter Minto, all of which presented attractions which I could not resist."

Having finished his course at Princeton, he returned to New York and resumed his medical studies, where they had been interrupted shortly after the occurrence of the Doctors' Mob. He now had the advantage of being able to give them his undivided attention, and he has no little to say in praise of the medical opportunities which New York City at that time afforded. He did not consider, however, that he had exhausted medicine, merely because he had attended the lectures of New York professors, but knowing, by reputation, the distinguished professor of medicine in Philadelphia, he resolved to visit that city and take advantage of the stimulus that would be afforded by contact with other distinguished medical minds. In this we see once more that eclecticism which, as we have said, is no longer considered the proper method, though often occurring, in fact being almost the rule, in the German universities, and undoubtedly making for a breadth of knowledge and a development of critical faculty that cannot help but prove helpful in the after career. Dr. Hosack's own account in this matter seems worth while giving here because it shows the independent character of the man and the student only just entering upon manhood and his deep-seated desire for knowledge and the deep-seated desire for the opportunities of gaining it:

"I attended the lectures on Anatomy and Physiology, delivered by Dr. Wright Post; those on Chemistry and Practice of Physic, by Dr. Nicholas Romayne, and the valuable course on Midwifery and the Diseases of Women and Children, by Dr. Bard. I also attended the practice of physic and surgery at the almshouse, which then offered the only means of clinical instruction in this city; they were, however, very ample, the house being daily visited by Dr. Post, Dr. William Moore, Dr. Romayne and Dr. Benjamin Kissam. In the autumn of the year 1790, being desirous of obtaining all the advantages of instruction which the United States at that time afforded, I proceeded to Philadelphia, the medical school of which had already acquired great celebrity from the learning of its professors, especially Drs. Shippen, Rush, Kuhn, Wistar and Barton. At that time a division already existed among the Faculty, which led to the institution of a medical college as a rival school to that connected with the university, and not a little contributed to the benefit of both, and the ultimate advancement of the science of medicine in Philadelphia.

I entered as a regular pupil, and attended all the courses of lectures delivered during the winter in the university. I also attended those delivered on the Theory and Practice of Physics, by Dr. Rush, then a professor in the College of Philadelphia, as well as his clinical instructions in the Pennsylvania Hospital. In the summer of the succeeding year, after the usual private and public examination, I was admitted to the degree of Doctor of Medicine in the University of Pennsylvania, upon which occasion I duly defended an inaugural dissertation on cholera morbus, in which I endeavored to illustrate the doctrine of Dr. Kuhn on that subject, that an acid in the primæ viæ, chiefly the effect of the use of ascessants, was the most usual proximate cause of that disease. Upon that subject my views have been materially changed since that period."

One experience of Dr. Hosack's medical student days, his part in the so-called Doctors' Mob, deserves to be recorded in particular because it shows the temper of the times. We venture to give two rather different descriptions of it because they demonstrated how differently a striking event may appeal to two otherwise sympathetic stories.

In his very interesting narrative of medicine in America, James Gregory Mumford, of the Harvard Medical

School,[1] gives the following picturesque account of what came afterward to be known as the Doctors' Mob:

"In New York medical teaching languished until 1813. Though there lived and practised in the city a number of first-rate men, their dissensions and jealousies for years prevented medical progress. The hospital made some history, however, and was launched anew after nine years of labor. In the interval between 1782 and 1791 the Society of the Hospital held annual meetings and elected officers, but the buildings were used for almost any purposes other than those for which they were erected. Sometimes poor folk were given the rooms as lodgings. One of the faculty (Bayley) gave some anatomical demonstrations there and did some operating, and for a few months the legislature sat in the hospital, but the most conspicuous event connected with the place during this dreary period was the once famous 'Doctors' Mob.' It was in the anatomical era, when students and doctors were making dissections there. There was hard feeling and suspicion about their finding bodies for the work—natural enough, as any one must admit who reads the old demonstrators' own statements of their modus operandi in procuring material. They seem to have rifled graves whenever they could, regardless of sex or condition, and most people conceived an 'ignorant prejudice' against having their mothers and sisters dissected by a parcel of callow students.

"The 'Doctors' Mob' made itself 'famous' on Sunday, April 13, 1788. While the dissecting was under way, a boy peeped in at the window, and some jocular individual who spied him from the room waved a dead arm at him, so the boy said. At any rate, he was duly impressed, and confided his experience to whomsoever would hear him, with the result that an angry crowd tried to take over the custody of the building and break up the anatomical course. The students and doctors thought it prudent to run away, and found sanctuary in the jail, with the mob after them. Then John Jay came upon the scene, exactly how or why does not appear, and peppery old Baron Steuben and Mayor James Duane, reading the riot act, backed by a handful of militia. The mob proceeded to hustle the dignitaries and knocked down Baron Steuben, who lost his temper and called out, 'Fire, Duane, fire!' The militia fired, seven rioters were killed, many were wounded, and the rest went home. That was the famous 'Doctors' Mob,' and the doctors got no sympathy. The governors denied their responsibility for the doings at the hospital, sent in a bill of twenty-two pounds seven shillings tenpence to the breathless doctors, and, after collecting the money, closed up the buildings.

"After that the governors seem to have come to their senses, and really determined to apply the hospital buildings to their original purposes. At any rate, within three years the reform had been accomplished, and in January, 1791, the hospital was again opened. Samuel Bard helped the starting and so did Malachi Treat."

That the "Doctors' Mob" was a much more serious affair for those who were voluntary or involuntary participants in it might be judged from this account, and will be readily realized by any one who reads the paragraph with regard to it in the memoir of Dr. David Hosack, published by his son, Alexander Eddy Hosack. At the time Dr. Hosack was pursuing his studies in the regular course at Columbia College. His son says:

"Finding his time not fully occupied in the commencement of the junior year, he resolved upon the study of medicine, and, accordingly, in May, 1788, entered as a private pupil with the late Dr. Richard Bayley, an eminent surgeon in New York. He had scarcely begun his studies before the celebrated 'Doctors' Mob' occurred, which threatened serious results to those concerned; it arose in consequence of the imprudence of some of the students carelessly pursuing dissection in the building upon the site since occupied as the New York Hospital. This mob caused many of the professors to absent themselves from the city, and others to seek shelter in the city jail. Mr. Hosack, with the rest of the students interested, learning that the mob had seized upon and demolished the anatomical preparations found in the lecture-room above referred to, repaired immediately to Columbia College, with the view of saving such specimens as were to be found in that institution. Before reaching the college, however, and when on his way in Park Place, he was knocked down by a stone striking him on the head; he would in all probability, have been killed had it not been for the protection he received from a neighbor of his father, Mr. Mount, who was passing at the time, and took care of him. He never saw that gentleman afterward without feeling and expressing his gratitude to him for his kindness."

SOCIETY PROCEEDINGS.

ILLINOIS STATE MEDICAL SOCIETY.

Fifty-fourth Annual Meeting, held at Bloomington, May 17, 18 and 19, 1904.

The Society met in the Unitarian Church, under the presidency of Dr. Carl E. Black, of Jacksonville, Ill.

The scientific work was divided into two sections, medical and surgical.

Brief abstracts of many of the papers are herewith submitted.

Contagiousness of Typhoid Fever and the Vitality of the Typhoid Germs.—Dr. F. D. Rathburn, of Galesburg, read this paper. He spoke of the vitality of the typhoid bacillus in the living body, and discussed the length of time after convalescence when the patient is liable to communicate the disease by the excreta. He also pointed out the vitality of the germs outside the living body, and their power to generate in soils and other favorable media. He emphasized the importance of disposing of the excreta in order to prevent the spread of the disease. The germ has been shown to remain active for a considerable length of time after the fever in (1) posttyphoid abscess; (2) the urine; (3) contents of lung cavities; (4) gall-bladder, and (5) evacuations from the bowels. The proper disposition of the excreta is the only method of prevention. Cremation he considered the best method. When cremation is not practicable, he suggests that the excreta be deposited in heavily glazed earthenware receptacles, treated with germicides, and buried deeply at a distance from the water supply.

Mental Disorders of Neurasthenia.—Dr. Frank P. Norbury, of Jacksonville, said that the mental symptoms of this disease are of importance in every case. They vary from slight mental incapacity to pronounced state, "borderline" to insanity. The principal symptoms mentioned are introspection, imperative conceptions, morbid fears, irritability (marked by absence of symmetry), nagging, fault-finding, and excessive emotional outbreaks. The physical factors and differential diagnosis were discussed at length. The treatment consists of isolation, systematized rest, with adjuvants indicated in each case; also treatment of associated physical factors.

Treatment of Appendicitis from a Pathological Standpoint.—Dr. E. C. Franing, of Galesburg, pointed out the differences of opinion on the treatment from a clinical standpoint. He spoke of the

treatment of the various forms of the disease, paying particular attention to the Ochsner and operative treatments.

Relation of Medicine to Surgery.—Dr. James E. Coleman, of Canton, thinks that whereas in former days the surgeon was first and foremost a fine physician, now surgeons neglect medicine. He discussed some avoidable surgical affections of the ovaries.

Leucemia; with Special Consideration of Its X-ray Treatment.—Dr. Everett J. Brown, of Decatur, gave reasons for reporting and standpoints taken in regard to this disease. He gave the history of a case of splenomedullary leucemia having a leucocyte count of 800,000, with a greatly enlarged spleen, in which the use of the X-ray caused the disappearance of all symptoms. He considered the cases in literature so treated, and presented a summary.

Polyneuritis.—Dr. L. Harrison Mettler, of Chicago, stated that multiple neuritis is a much-abused term. The general conception of the disease and the text-book descriptions of it are far too narrow. It is a disease more or less of the entire nervous apparatus. He spoke of the central and peripheral types of the disease; of the relative significance of the interstitial and parenchymatous disease processes. He spoke of the relative importance of the particular etiological influences, and pointed out the clinical indications of the extensive nature of the disease. Pathological proofs were advanced. He referred to the differential diagnosis of types of the disease requiring variable treatment.

Dr. Thomas H. Bath, of Bloomington, read a paper in which he brought forward successive scientific data confirming the mosquito as the definite host of malarial fever.

Dr. James Moreau Brown, of Chicago, presented a general consideration of speech disorders, laying particular stress on etiology and treatment, and then discussed the so-called stammering institutes. He gave reasons why cases of this character should be cared for by the physician.

The Pneumonia Problem.—Dr. Arnold C. Klebs, of Chicago, spoke of investigations into statistical data regarding this disease, and its increase in the United States and abroad. He made a comparison of non-tuberculous respiratory diseases, and tuberculosis, both clinical and statistical. He pointed out the dangers of pneumonia to the individual and to the community, and how they can be met.

Dr. Charles J. Whalen, of Chicago, referred to the increasing prevalence of the disease, and gave a comparison of mortalities from pneumonia and tuberculosis. He pointed out the possibility of making headway against the disease from a prophylactic standpoint. The public should be educated as to the dangers of pneumonia. There is no known specific for it. Expectant treatment is the most satisfactory, and among other things he mentioned rest, ventilation, sponging, elimination, poultices and glycerin; also the value of antipyretics, serum therapy, venesection, arterial sedatives, oxygen, opium, creosote, normal salt solution, suprarenalin, stimulants, expectorants, etc.

Brain and Sinus Diseases Resulting from Purulent Otitis Media.—Dr. A. H. Andrews, of Chicago, said that brain and sinus complications are more common that is generally supposed. He stated that pus in the mastoid escapes in one of six directions. The intracranial complications may be general meningitis, extradural abscess, cerebral abscess, cerebellar abscess, and sinus disease. He expatiated at length upon the symptoms and treatment, followed by a report of cases.

Joint Affections as Viewed by the Internist; Their Classifications and Brief Considerations.—In this paper, Dr. August F. Lemke, of Chicago, pointed out the distinguishing features between the joint diseases known as the rheumatic arthritides, and the group known as arthritis deformans. He discussed the treatment of some of the more important joint lesions.

Dr. H. W. Chapman, of Whitehall, reported a case of mastoid operation which embraced some unusual features.

Dr. R. R. Campbell, of Chicago, considered the differential diagnosis between pseudomembranous angina of syphilis and angina of diphtheria. He pointed out the difficulties encountered, referred to the treatment, and the results.

Dr. Norval H. Pierce, of Chicago, reported additional cases of sigmoid sinus thrombosis from middle ear suppuration.

Middle-Ear Suppuration.—Dr. Willis O. Nance, of Chicago, in discussing this disease, stated that acute otitis media of infancy and early childhood was frequently an unrecognized process. The recent investigations of Ponfick, Barth, and others demonstrate that a large proportion of infants and young children at some time suffer from middle-ear inflammation. The dangers from non-recognition were pointed out; also the close relationship between acute purulent otitis media and acute infectious processes other than diphtheria and scarlet fever, namely, gastro-intestinal disturbances and bronchopneumonia. He mentioned the structural variations between the infant and adult middle ear, and the diverse characteristic manifestations of inflammation in each. Considerable attention was paid to the diagnosis and treatment of acute infantile otitis media.

Ulcers of the Cornea.—Dr. William H. Wilder, of Chicago, in speaking of infectious ulcers of the cornea, said that the underlying cause is to be sought in impaired vitality of the tissues from a general local depraved nutrition. The active cause is usually some trauma which is supplemented by a virulent infection. The source of the infection is frequently in the tear sac. He emphasized the importance of prompt recognition and active treatment. Cauterization of the ulcer plays a prominent rôle in the treatment, as well as constitutional measures.

Cholecystitis.—Dr. M. L. Harris, of Chicago, in dicsussing this affection, spoke of the influence of microorganisms in its etiology. He referred to the great length of time microbes may remain active or retain their vitality in the gall-bladder. He pointed out the great frequency with which cholecystitis is mistaken for other conditions. He referred to the advantages and necessity of drainage of the gall tract in cases of cholecystitis, and the length of time drainage should be continued.

Kidney Surgery.—Dr. Arthur Dean Bevan, of Chicago, gave a brief historical review of this subject, and mentioned the pathological conditions warranting surgical interference. He likewise mentioned the means of diagnosis, and in discussing the surgical treatment, referred to nephrorrhaphy, nephrotomy, enphrolithotomy, nephrectomy and plastics on the kidneys and ureters. Attention was directed to the prognosis after kidney operations.

Some Interesting Cases of Subcutaneous Injuries of the Abdominal Wall and Viscera.—Dr. D. N. Eisendrath, of Chicago, pointed out the necessity for a more general knowledge of the subject by the general practitioner as well as the surgeon, saying that many lives might be saved by prompt recognition of serious injuries of the abdominal viscera in which there is

only slight injury of the skin. He divided the abdominal organs into solid and hollow viscera. He alluded to the greater amount of protection of certain organs; discussed the manner in which injuries occur, and the mode of examination for the purpose of making a diagnosis. He reported a number of cases, analyzed statistics, and drew deductions from the same.

Fissure in Ano.—Dr. J. Rawson Pennington, of Chicago, discussed the office treatment of fissure in ano. He referred to the etiological factors and pointed out the more important symptoms of the affection. After speaking of the diagnosis, he considered the non-operative and operative treatment, and mentioned divulsion of the external sphincter without the use of the ordinary general or local anesthetic.

Dr. S. C. Stremmel, of Macomb, read a paper in which he made a plea for early and interval operations in cases of appendicitis. He presented some interesting statistics.

Pregnancy and Appendicitis.—Dr. Charles B. Reed, of Chicago, spoke of the reciprocal influence existing between the inflamed appendix and the fruit sac, and of the disastrous consequences for the gestation and fetus. He detailed the mortality statistics of this condition as compared with other serious complications of pregnancy. The difficulties of diagnosis during pregnancy were emphasized. He spoke of the desirability of adopting a definite mode of procedure in these cases.

Dr. J. F. Percy, of Galesburg, reported a case of intestinal obstruction. He insists upon early operation, and outlined the best methods of treatment before consent for operation is obtained. He pointed out the wisdom of temporizing operative methods in a case of intestinal obstruction where exhaustion is extreme.

X-ray Therapy.—Dr. Charles D. Center, of Quincy, gave a review of the cases reported to the Society one year ago, with some additional notes used as illustrations. He pointed out the difficulty of telling before treatment whether benefit will follow the application of the X-rays or not. He reiterated that more is claimed for the rays therapeutically than is justified, saying that this claim arises from some apparently brilliant results which are not supported clinically by the lapse of time.

Placenta Previa.—Dr. Henry F. Lewis, of Chicago, discussed some practical points in the diagnosis and treatment of placenta previa.

Antenatal Pathology.—Dr. Charles F. Paddock, of Chicago, in a paper on antenatal pathology, stated that there is a fetal pathology which has for its etiology ceratin factors which could have been prevented. Every case of pregnancy should be considered as an abnormal condition, requiring the advice and attention of a physician. A neglect to do this often means injury to the fetus. The fetus suffers from a hereditary taint, notwithstanding the possibility of such a condition being known by the physician and one or both of the parents. The author under treatment discussed the preventive and curative measures.

Dr. Carl Wagner, of Chicago, under the head of "Porro Operation," described a modification which consists in reversing the course of the operation. He described a method of controlling hemorrhage; pointed out the indications for the operation, and reported three cases, with recoveries.

Symphyseotomy in Persistent Mentoposterior Face Presentation.—Dr. E. B. Montgomery, of Quinsy, read a paper on this subject and reported a case. The author was unable to find very much literature regarding the use of symphyseotomy in such cases, although all the textbooks on obstetrics express themselves favorable to its performance. He gave an abstract of the report of seven such cases made by Pinard, in 1902, and detailed an account of his own case, which was successful as regards the mother, although the child perished from asphyxia shortly after birth.

Dr. Palmer Findley, of Chicago, spoke of the value of systematic blood examinations in gynecology; while Dr Albert Goldspohn, of Chicago, pointed out the reasons why digital exploration through the internal inguinal rings should be made in conjunction with every Alexander operation.

Dr. Geo. W. Newton, of Chicago, spoke on cystic tumors of the ovary. He discussed the histogenesis, etiology, symptoms, and emphasized the importance of early and correct diagnosis by the citation of illustrative cases. He likewise spoke of the accidents to and changes in ovarian cysts.

Dr. Charles B. Horrell, of Galesburg, described a rather unique case of imperforate hymen in a fairly rugged, rather athletic girl of sixteen years. She was a bicycle rider, etc., and was healthy, one in whom naturally an imperforate hymen would not be suspected, but the patient suddenly exhibited an abdominal tumor the size of a six months' gravid uterus. Examination revealed imperforate hymen, and an incision released about two quarts of grumous black blood, with perfect relief. He said that although this condition is rare, it may occasionally be found.

Dr. E. Wyllys Andrews, of Chicago, exhibited a phantom or model for illustrating herniotomy and suture work on the abdominal parietes. He emphasized the importance of suturing abdominal wounds layer by layer, and pointed out the difficulty of showing all steps of the closure to large audiences. Students get inadequate notions of the real care necessary. Herniotomy can hardly be shown to more than eight or ten observers. He spoke of the value of cloth in layers to imitate abdominal fascia. The parts are almost perfectly reproduced in large size. The author's radical cure for hernia was demonstrated.

Immediate Abdominal Section.—Dr. Denslow Lewis, of Chicago, in a paper with this title, said that the opinion is concurred in that increased facilities for surgical work and the multiplicity of hospitals in country districts often induced practitioners to undertake important abdominal operations without proper qualification or adequate experience. It is conceded that the usual postgraduate instruction may be a means of advertisement for the instructor rather than an honest attempt to teach the student-practitioner the details of operative technic. It is also admitted that many of those in attendance for a few weeks at post-graduate schools only too often seek a superficial knowledge of recent advances, and a respite from their everyday work, and but few are actuated by a sincere desire to add to their actual surgical capability. Nevertheless, it is urged that under certain conditions abdominal section must be undertaken by the practitioner in charge, for without such intervention the patient's life is jeopardized and in some instances the result is inevitably fatal. The principles of asepsis are simple and easily applied anywhere. The author cited cases from his recent experience in ectopic gestation, appendicitis, obstruction of the bowels, and other conditions where the demonstration has been made that immediate operation alone can save life.

Dr. J. N. Stealy, of Freeport, discussed the use and abuse of drainage. The purposes of drainage were set forth, also the indications and advantages, as against the disadvantages and bad results of drainage. The author believes that in the present day the inclination is for less drainage.

Tuberculosis.—In the section on Practice of Medicine, there was a splendid symposium presented on tuberculosis. Dr. George W. Webster, of Chicago, spoke of the mortality of the disease in Illinois for the years 1902 and 1903. Dr. Charles L. Mix, of Chicago, pointed out the factors causing tuberculosis, and aiding its spread. He offered suggestions for its prevention. Dr. Frank Billings, of Chicago, discussed the diagnosis of pulmonary tuberculosis; Dr. Robert B. Preble, of Chicago, the treatment. Dr. Homer M. Thomas, of Chicago, followed with a paper in which he pointed out the annual economic loss to the State of Illinois from this disease. Dr. Harold N. Moyer, of Chicago, discussed the duty of the State in restricting tuberculosis.

In the Section on Surgery there were symposia on eclampsia and carcinoma.

The following officers were elected for the ensuing year: President, Dr. Wm. E. Quine, Chicago; Vice-Presidents, Dr. H. C. Mitchell, Carbondale, and Dr. J. F. Percy, Galesburg; Secretary, Dr. E. W. Weis, Ottawa; Treasurer, Dr. Everett J. Brown, Decatur.

Rock Island was selected as the place for holding the next annual meeting.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, held at the New York Academy of Medicine, June 13, 1904.

The Vice-President, R. E. Van Gieson, M.D., in the Chair.

Clinical and Other Features of the Present Epidemic of Cerebrospinal Meningitis.—The first paper of the evening was read by Dr. Henry W. Berg, on this subject. At all times, he said, the disease is endemic in New York, the average number of deaths from it being, for Manhattan and the Bronx, in late winter and spring, 25 per month and at other seasons sometimes as low as 10 per month. The Health Department reports show that the present epidemic is much more severe than that of 1893, the number of deaths in the boroughs just named having amounted to 306 in the month of May. The disease is now gradually declining. The proportion of fatal cases among older children and adults is very much greater in this than in any other epidemic the statistics of which Dr. Berg has seen. In this, as well as in all other recorded epidemics in this country, a very large increase in the deaths from pneumonia, occurring at the same period, has been observed. This fact is of extreme interest from an etiological standpoint. As is well known, the bacteriological cause of epidemic cerebrospinal meningitis is the *Diplococcus intracellularis meningitidis*, isolated by A. Weichselbaum; and yet, in a publication in 1887, even Weichselbaum conceded that a proportion of the cases of this disease are due bacteriologically to the *Diplococcus pneumoniæ*, the most frequent etiological factor in idiopathic cerebrospinal meningitis also. Whether the Weichselbaum meningococcus is the exclusive cause of all epidemics of cerebrospinal meningitis appears to be still unproven. One of the earliest of Dr. Berg's cases in the present epidemic was one of lobar pneumonia complicated by or complicating cerebrospinal fever. Resolution of the pneumonia occurred after six days, but the cerebrospinal symptoms continued, and the patient, a girl of eighteen years, died at the end of four weeks.

In the epidemic of 1893 and in Councilman's report of the Boston epidemic he could find no history of more than one case in one family, but in the present epidemic in a number of instances he has had two cases in the same family, and in one family there have been as many as three cases. While these cases seem to point to the contagious character of the disease, we know but little of the method of the contagion. It is quite generally conceded that the germ probably enters through the nasal passages and is spread by the lymphatics to the dura and subarachnoid spaces. It is possible, also, that it is carried by the capillaries to the site of the lesion in the brain and spinal cord, although a general infection of the blood (septicemia) does not occur, nor, according to Councilman, has the organism been found in cultures taken from the blood. The meningococcus, however, has been found of feeble growth, and Dr. Berg does not believe this disease to be as contagious, directly or indirectly, as typhoid is, through the stools, or even as pneumonia, through the sputum. The lesion is primarily located in the membranes of the brain and cord, and the involvement of the spinal membranes is much greater and more general than in any other form of meningitis. Along the base of the skull the infection extends to the cranial nerves and the fifth nerve ganglia; it also extends into the spinal nerve roots and spinal nerves, giving rise to symptoms dependent upon inflammation and degenerative changes. Inflammation of the lungs, bronchi, tonsils and middle ear are met with as the result of direct invasion by extension from the nasal cavity and cerebral meninges. The diplococcus can be found wherever the infection extends.

Several Classes of the Epidemic.—In this epidemic the cases he has seen can be divided into three classes: (1) Chronic cases (the most frequent), beginning with acute symptoms, which gradually assume a chronic character, with acute exacerbations. In any one of these exacerbations the patient may die, or the symptoms may again subside. After weeks and even months of illness death may result, or recovery, complete or incomplete, may occur. In some instances there remain more or less complete and permanent disabilities of the eyes or ears, sensory and motor paralyses, or psychical disturbances. (2) Cases (next in frequency) which throughout their course are of an acute character, lasting from one to four weeks and terminating either in death or in recovery, which as a rule is absolute. (3) Fulminating cases, lasting from a few hours to three or four days, which are characterized by most foudroyant symptoms and terminate fatally. The abortive type of cases, lasting for a few hours or a day or two, with recovery, he has not seen, probably because he does not consider the diagnosis confirmed until the diplococcus has been found in the fluid obtained by lumbar puncture. The disease in this epidemic has had no prodromal stage. The acute symptoms have been those of a febrile disease involving the brain and spinal cord: Severe headache, stiffness or even rigidity at the back of the neck, and in most cases in adults, in all in children, vomiting. Pain in the muscles of the back and extremities are also complained of by most of the cases, and hyperesthesia is observed in all except the foudroyant ones. There is generally much trembling, as though from chilliness, and the patient has a tendency to fall into stupor. Ordinarily the temperature is high, but in exceptional instances low. The curve, which has nothing distinctive, is characterized by sudden and extensive variations. The patient early assumes a peculiar position, which is maintained even during delirium and semi-coma. He lies on either side, with the thighs flexed and the abductors spasmodically contractured. The legs are flexed upon the thighs, and the arms, flexed at the elbows, are brought over the front of the chest, while the head is extended backward.

Symptoms.—The symptoms due to inflammation of the brain and medulla and their meninges, and to neuritis of the cranial nerves, are headache, slow pulse, hydrocephalic cry, tache cerebrale, vertigo, convulsions, delirium, coma, coma vigil, Cheyne-Stokes respiration, photophobia, abnormalities of the pupil, ptosis, strabismus, diminished or absent conjunctival reflex, deafness, facial paralysis, hemiplegia, monoplegia, paraplegia, etc. Macewen's symptom is present in advanced cases of coma or semi-coma due to distention of the ventricles of the brain; percussion of the skull one or two inches behind the junction of the frontal, parietal and temporal bones giving rise to a clearer note than is obtained over other parts of the cranium. The joints, particularly the knees, may be affected, the trouble varying from simple pain on motion to all the manifestations present in acute articular rheumatism. That these joint lesions are not toxic but trophic in character was shown by one of Dr. Berg's cases, a child eight months old, in whom a well-marked spinal arthropathy, or Charcot's joint, developed. There soon resulted subluxation of the joint surfaces upon each other, with total destruction of the ends of the bones. This case, so far as he knew, was unique. Absence of patellar reflex is due to increased intraspinal pressure, and affords an indication for a repetition of lumbar puncture. The increased leucocyte count in the blood (18,000 to 30,000) is a valuable symptom, which serves to differentiate these cases from tuberculous meningitis and typhoid fever. The diagnosis may be made absolutely by the finding, by culture, of the meningococcus in cerebrospinal fluid withdrawn by means of lumbar puncture. Kernig's symptom is the most reliable physical sign of the disease which we have, and he has never seen it absent in the present epidemic. It is obtained by placing the patient upon the back, flexing the thigh at right angles with the abdomen, and then extending the leg upon the thigh thus flexed. If Kernig's symptom be present, the complete extension of the leg upon the thigh cannot be accomplished. The patient will cry out, even when semi-comatose, long before the leg is brought to a line with the thigh, and the spasmodic muscular resistance cannot be overcome even by forcible efforts. As the Kernig diminishes, the prognosis improves. This symptom, it should be stated, is not limited to cerebrospinal fever, but is present in other forms of meningitis also. It is generally unequal on the two sides, and sometimes is only unilateral. Very little diagnostic importance should be attached to the Babinski reflex. It is true that in some cases of meningitis the other toes are flexed and the great toe is extended, when the plantar surface of the foot is tickled; but this symptom occurs in some healthy children and in children suffering from other diseases, while it is by no means constant in cerebrospinal meningitis.

Treatment.—Our therapeutic resources in this disease have not kept pace with the advance of our knowledge of symtomatology and pathology. Owing to our incomplete knowledge concerning the source of the contagion and the methods by which it is transmitted, even the prophylactic treatment is uncertain. It has been shown, however, that the meningococcus is one of the most resistant of organisms, retaining its life for a long time; so that as a dust it can readily be carried in the air, and in this way produce infection. Therefore, cleanliness in the sick-room, the careful removal of the discharges from the patient's nose and eyes by cloths or gauze which can be destroyed, the separate boiling of towels, clothing and bed-clothes, and the careful and frequent washing of the hands of attendants and visitors should be employed as safeguards to prevent the immediate carrying of the contagion from the sick to the well or the transmission of an individual contagion through the air. So far as the active therapy is concerned, there is little hope of the production of an anti-meningococcic serum, since it has been found very difficult to produce immunity with cultures of this organism even in the smallest animals. In the Lisbon epidemic Bettencourt and Franca treated their cases by injections of lysol into the spinal canal, with a death rate of only 40 to 45 per cent.; but in Spain the mortality should naturally be smaller than in colder and moister climates. Dr. Berg's usual method of treatment consists of lumbar puncture, repeated whenever, after a period of improvement, the temperature again rises and symptoms of increased intracranial and intraspinal tension occur. If the cerebrospinal fluid flows from the canula in a continuous stream under tension, the withdrawal of 15 to 30 cc. will do much good. Internally he gives sodium iodide in considerable doses: 5 to 10 grains every three hours to a child over a year old, and 15 to 30 grains every three hours to adults. In adults and older children mercurial ointment is rubbed into the back of the neck and spine, and in infants oleate of mercury into the anterior fontanelle. With these methods, together with the treatment of symtomatic indication, 40 per cent. of recoveries may be expected. Ice-bags should be applied to the head, neck, and spine, and if the temperature rises above 103° F. a warm bath is used for five minutes at 80° and five minutes more at 90°. Care should be taken to guard against bed-sores and cleanliness of the conjunctiva and nose will tend to prevent panophthalmitis and deeper infection through the nasal cavities. Plenty of fresh air and sunlight are essential, and if the eyes are affected they should be protected by means of a screen or eye-shade, but, as is the usual custom, by darkening the room.

Abortive Cases.—Dr. Andrew von Grimm said the warm weather has a certain beneficial influence in epidemics of cerebrospinal meningitis, because the hygienic surroundings of the tenement-house population is better then. The period of incubation has been determined as between three and seven days. The infection takes place not only through the nose and mouth, but also the conjunctiva. He has had five abortive cases: in all of them a positive diagnosis was made by the bacteriological finding. In the treatment, sodium salicylate particularly had seemed to be of service. He had never observed any benefit from the use of mercurial ointment or Credé's ointment. In three cases he had tried the plan of producing an abscess by injecting about 15 cc. of oil of turpentine. If there was any disease in which an expectant treatment was justifiable it was certainly this.

The Diplococcus Found in the Blood.—Dr. Henry P. Loomis said he had seen thirty-five cases of the disease at the New York Hospital. In all of them the specific organism was present in the fluid derived from lumbar puncture, and it was interesting to note that in four instances it was demonstrated in the blood by competent bacteriologists. The mortality was very high: 66 per cent. in children and 61 per cent. in adults. The treatment was very disappointing. While lysol injections did no harm, he had not seen any results from it, and there appeared to be nothing in this method which offered any ground for hope. In one case, hopeless at the time, argyrol was injected. The patient died the next day, and at the autopsy evidences if pigmentation all over the brain were found, showing that the drug had circulated freely in the cerebrospinal fluid. He thought the abscess treatment mentioned by Dr. von Grimm might perhaps be attended with good results in some cases.

The Nursing One of the Most Important Points in the Treatment.—Dr. Wm. M. Leszynsky said it had been contended by many that when lysol was employed it never got beyond the site of the injection. He was therefore very glad to hear of the last case mentioned by Dr. Loomis, as it showed conclusively that substances thus injected do reach the various parts of the cerebrospinal tract. In the case of one child he had injected a one per cent. solution of lysol, and it was the only instance of complete recovery among the cases which he had at the time. From this one case, however, he would not draw any conclusion as to the benefit of this agent in general. It seemed to him that one of the most important things was the nursing, and in hospital practice it was very difficult to secure adequate attention to this. Even the chronic cases required the same care as typhoid fever patients. Kernig's symptom was found in all the cases; it is merely a confirmatory sign. One thing he could not understand, the attitude of some toward lumbar puncture; they contended that it was of no benefit. The procedure, when properly performed, is entirely harmless, and it is certainly of great diagnostic value at least. In hospital practice he thought it should be done in every case. He had not seen a petechial eruption in any instance, nor had he met with a single case of the fulminating type. In one case, however, the diplococcus was found after death in a patient who had suffered from intermittent trismus, but had no opisthotonos or rigidity of the neck.

Dr. Van Gieson read a paper on Infant Feeding.

Cow's Milk for Infant Feeding.—Dr. Augustus Caillé read a paper on this subject. In our attempts at the modification of cow's milk we are guided, he said, by the following fundamental considerations: (1) Reduce the proportion of proteids by dilution. (2) Increase the quantity of fat, originally sufficient but reduced by the necessary dilution. (3) Increase the sugar and salt, likewise made sufficient in amount by the dilution. (4) Sterilize or pasteurize in warm weather and for special cases. Milk food ordered by prescription according to the percentage method and supplied by the laboratory has given him very excellent results, but the same gratifying results he has obtained from home modification by simple dilutions of top milk. For various reasons the modifications of cow's milk, whether made in the household or in the laboratory, will not give uniformly good results, no matter how accurate we may be in our manipulation of percentages. We cannot convert cow's milk into mother's milk, however scientific we are; we are obliged to use cow's milk as nature furnishes it to us. With proper hygienic management, however, clean cow's milk, properly diluted or modified, will suit the vast majority of bottle-fed infants, provided they are not over-fed. The following simple method of home modification has been practiced by Dr. Caillé for the past twenty years: If a quart bottle of average good milk stands for four hours the upper half of the milk will contain about twice as much fat as the milk before standing. This point of so-called top milk is decanted and forms the basis of bottle food for home modification. By diluting this top milk in various proportions we obtain a food of various strengths as regards fat and proteids. The deficiency of salt and sugar is readily made up by the addition of these substances, and a food is thus prepared which will vary in composition according to the requirements of the child to be fed. Schedules were given for the feeding of infants of different ages.

In a difficult feeding case cow's milk should be discontinued for a short time, and cereal decoction and white of egg substituted. In resuming cow's milk we begin with a low strength, and gradually work up to full strength milk, care being taken to avoid overfeeding. Digestion is best stimulated by carrying children out of doors, and not by drugging. An idiosyncrasy for cow's milk in proper dilution should not be suspected until after the child has had proper hygienic management. Infants and children who are kept indoors in cool and cold weather, and compelled to breathe the air of overheated and stuffy living apartments, will not digest well, no matter what they feed on. Idiosyncrasy for cow's milk is managed by selecting some substitute food, if possible the breast of a wet-nurse. In some cases whey with cream and cereal decoction will answer.

A Simple Plan of Home Modification.—Dr. H. D. Chapin thought the biological question quite as important, if not more important, than the chemical. In the plan which Dr. Chapin has adopted a constant ratio between the fats and proteids is maintained. In a bottle of milk which has been allowed to stand for six hours in a cool place we find three layers. In the first (of 9 ounces) the ratio is 3:1, in the second (of 16 ounces), 2:1, and in the third (of 20 ounces), 1½:1. In order to get a combination of the three layers a dipper is employed which holds just one ounce. Unless the method directed for home modification of milk is simple it will not be carried out. By watching the stools such alterations can be made as may be indicated. His experiments did not agree with those of White, for he found that a dextrinized gruel makes a better diluent than the plain cereal. We know that young infants can digest a small amount of starch, but it is not beneficial for them to do so.

The Work of the Chemist Not Sufficiently Appreciated.—Dr. E. H. Bartley said that as long as there were babies this subject would give us difficulty. He thought it often the case that the chemist was not given his just due. Such a discussion as this was brought about by the fact that the chemist in the laboratory had demonstrated that the caseins are different, and has shown how to get rid of the violent effects of the paracasein or pseudonuclein. If we are to make progress the careful chemical study of cow's milk is requisite. No chemist ever intends the method he recommends to be the only one. It is recognized that idiosyncrasies exist which will prevent any one kind of food from being invariably satisfactory.

Dr. Charles G. Kerley said it was universally recognized that cow's milk must be used as a basis in substitute feeding. While no one plan of preparing it would suit all babies, he thought we could arrive at one which would be satisfactory for the majority. He would like to say a word in favor of the laboratory. Whenever it was possible he always ordered laboratory modified milk, and this was his practice among the better class of his patients. In a second class of cases he used split milks. In a third class of cases, infants in institutions, the digestive condition had to be taken into careful consideration. In children with digestive weakness careful attention should be paid to the condition of the stomach, and not infrequently the greatest possible benefit could be derived from daily washing out this organ. Fresh air was essential.

The Essentials of Successful Artificial Feeding.—Dr. Theron W. Kilmer said that among the higher classes of women the nursing of infants at the breast was much less common than among their humbler sisters. The reasons for this he thought were (1) alcoholism, and (2) the strained and rapid mode of life. The successful practitioner is the physician who knows how to feed babies successfully. To secure success he mut pay special attention to three things: (1) The milk used, (2) the baby's stomach, and (3) the nursing bottle. As to nursing bottles, it is often assumed that

they are kept clean, when as a fact they certainly are not, and too much stress could not be laid upon the importance of this point.

ASSOCIATED PHYSICIANS OF LONG ISLAND.

Nineteenth Regular Tri-yearly Meeting, held June 18, 1904, at Central Islip, Long Island.

The President, James P. Warbasse, M.D., in the Chair.

The Care of the Infant.—Dr. Henry P. de Forest emphasized the importance of being fully prepared for the various accidents that might await the new-born infant. The following things should be in readiness: A bathtub partly filled with hot water (the household bathtub, if near, will suffice); two pairs of artery forceps, a curved needle with heavy silk, a tenaculum for baby's tongue, a gauze pad for insufflation. The mouth should be cleansed as soon as the head is over the perineum; this may prevent asphyxia from meconium, mucus or regurgitated blood.

Cord Around the Neck.—Formerly the current practice has been to exert every effort to disengage the cord, as soon as its pressure is seen or felt around the neck. The rule should rather be to remove it if this can be done quickly and easily. If the least difficulty is experienced, proceed at once to complete delivery, for children have been lost owing to delay in trying to remove the cord. Occasionally it is easy to slip the cord over the shoulders. If the cord is too short, in this case interfering with delivery, there is the danger of loosening of the placenta, with internal hemorrhage. By then clamping the cord with two artery clamps the cord may be cut between them.

Asphyxia.—The two most important points in the treatment of this condition are to clear the air-passages of mucus and to stimulate the child with heat and artificial respiration. The former may be accomplished by wiping the mouth and then resorting to insufflation of the mouth and nose. Artificial respiration may be performed while the child is in the bath of hot water, an attendant applying cold water to the chest and spine, and may be aided by rhythmic traction on the tongue. The alternation of hot and cold bath is not as good as the hot bath and artificial respiration. If not relieved by this, the child cannot be saved at all.

Atelectasis.—This may result from the acclusion of the bronchial tubes with mucus. It should not be confounded with bronchopneumonia resulting from the inhalation of mucus, milk or blood. Cyanosis is a more or less prominent but a later symptom. The treatment is heat and food.

Cephalhematoma.—If small, let child lie on side of head opposite to the swelling. If large, the head should be wrapped in a bonnet well padded with cotton. A favorable prognosis should be given, the tumor disappearing in three or four weeks. Absent treatment is the best. Hematoma of the sternocleidomastoid muscle may result from excessive traction on the head. Facial paralysis may interfere with feeding, in which case the child should be fed with the spoon or bottle. In the care of the eyes, silver nitrate has been found to be preferable to protargol. The supposed inability to nurse is frequently due to tongue-tie. The nurse should be instructed how to "blow baby's nose." As a dressing for cord, equal parts of zinc oxide and salicylic acid are efficient. It is preferable to omit the bath until the cord has fallen off, owing to danger of infection of the latter. Some children are stimulated by the bath and some are depressed; if the latter, the bath should be hotter. For tender nipples use a shield and recommend less frequent nursing. The application of comp. tinct. benzoin with a subsequent dressing of boiled sweet oil is efficient.

The discussion of Dr. de Forest's paper was opened by Dr. Harrigan, who urged the necessity of keeping the possibility of tetanus infection in mind, a condition which occurred twice in the speaker's practice. He also alluded to the importance of changing the child's position frequently, particularly at the breast, and cited instances of deformity resulting from incorrect posture having been mistaken for rickets.

Dr. Alfred Bell took issue with Dr. de Forest over the statement of the latter that if the infant's mouth is cleansed with boric acid before and after nursing it will never get sprue or stomatitis. He referred to instances in which these conditions occurred in spite of the most scrupulous care in the toilet of the infant's mouth. The care of the foreskin in the male infant is a very important point; all that is necessary is gentle separation with a small retractor. The speaker also alluded to the general apathy of the profession with regard to certified milk, in which only 30,000 bacteria per c.c. are allowed. The milk is fully worth twice as much as the price, 12 cents per quart, that is charged for it.

Dr. Kerr spoke of two points that make for the welfare of the child during the dawn of its life. It is sometimes heard that the child rebels against its natural food. This condition does not exist. The fault is excessive handling of the child, resulting in pressure over the stomach and bowel. The child should be rolled gently on the lap of the nurse in being dressed. The second point is that the ordinary pillow, becoming saturated with perspiration and milk which the infant occasionally regurgitates, becomes a good culture-medium for bacteria. In lieu of the ordinary pillow, a jute pillow should be used; the jute should be changed every day, as well as the slip. The expense of the jute is so slight that the very poor can afford it.

Dr. Chase said that it is undesirable to bathe the weakly child every day. A sponge bath with borax water is fully as efficient as the complete immersion.

Causes of Death Among Aboriginal Peoples.—Dr. F. C. Cook, the well-known Arctic and Antartic explorer, read an interesting paper on the above topic. It was contrary to the author's experience that alcoholism is the main cause of the extinction of the natives of this continent. One of the most potent causes that brings destruction to these people is the introduction of the various children's diseases by the white explorers and settlers, the adult, no less than the infant, population falling a ready prey to measles, scarlet fever and the like, which diseases break out with a virulence far greater than is seen among civilized people. The author explained this fact by suggesting that civilized races among whom the various infectious diseases raged with virulence in remote centuries, have inherited a passive immunity, while the savage, to whom these diseases are new, is not endowed with this immunity. Another disease which has proved destructive to the red man is tuberculosis. The causes of this increased susceptibility to consumption are found in the alteration of the mode of life of the Indians, the aggregations in villages, with crowding in unsanitary houses, with, in general, a tendency to degeneration rather than to uplifting. The substantial log house of the missionary settlement, with the probability of microbic multiplication from filth and sputum, is but a poor substitute for the wigwam in the native hunting ground. The author alluded to a virulent and fatal epidemic of parotitis among the natives of Alaska last year. To the Indian no blow is so hard as an acute infectious disease, to which he has not yet adapted himself. In 1896, an epidemic of measles occurred among the natives of Greenland with a mortality of 40 per cent.

Dr. Jas. P. Warbasse commented on that phase of

the subject which deals with the inherited immunities of civilized races, and suggested as an additional example of the latter the fact that the temperate nations of to-day passed through an era of intemperance during the early days of their history, as the result of which experience they have acquired a partial passive immunity against alcoholism.

Intestinal Antisepsis with Special Reference to Benzoyl-Acetyl Peroxide (Acetozone).—Dr. William H. Ross, of Brentwood, gave the results of his experience with this new intestinal antiseptic, particularly in typhoid fever cases, during the past year. It is an ancient fallacy that typhoid should be allowed to run its course. Discovered by Novy and Freel, of Ann Arbor, acetozone is a member of the large group of peroxides, possessing a greater germicidal power and a greater power of given-up oxygen. Biologically it is inert, but on taking up water it develops its power. It produces no constitutional effects and no poisonous effects, even in large quantities. It is germicidal in the strength of 1-33,000. The author used it in cases of purulent infection and gastro-intestinal fermentation and in thirteen cases of typhoid fever. In twenty-four hours 30 to 40 ounces of the saturated solution may be given, prepared by dissolving 15 grains in a quart of water, which is allowed to stand for two hours for hydrolysis to begin; it is then placed on ice. The taste may be veiled by means of lemon juice. The drug produces increased diuresis and a greater elimination of hippuric acid. The administration of salines enhance its value. The average amount of acetozone used in the author's typhoid cases was 210 grains. Its use was followed by an amelioration of symptoms. Two or three of the cases that were given up as hopeless by several physicians recovered after the use of this drug. The temperature fell in one or two days after its administration began, the stools improved, dryness of the tongue disappeared. In fact, in the previous three or four series of 13 cases, each of typhoid, treated by the speaker in former years, was the mortality less than 20 per cent. In the last series the mortality was nil, although some of the the cases were considered hopeless. The author admitted that 13 cases are insufficient to establish the value of a drug, but believed that his own experience, taken in conjunction with that of numerous other experimenters, furnish a very encouraging outlook in the the therapeusis of typhoid fever. The time for the purely expectant treatment has been outlived.

Dr. Leon Louria, in discussing the above paper, expressed strong doubts as to the efficacy of intestinal antisepsis. Osler in the last edition of his text-book has admitted the failure of this plan of treatment in typhoid fever. Bouchard, in the early '80's, was the first to attribute to intestinal auto-intoxication a rôle in the production of morbid conditions. Rossbach introduced this theory in Germany. Miller and Brieger state that, although the facts of anti-intoxication are beyond doubt, the bacteria are not alone responsible. The ethereal sulphates have not been recognized as criteria of intestinal auto-intoxication by German chemists. The clinical picture of this supposed poisoning with bacterial toxins may include vertigo, tetany with dilatation of the stomach, palpitation of the heart and urticaria, all of which are manifestations of conditions other than auto-intoxication. Moreover, these symptoms appear more frequently in women and children. Many of the symptoms of so-called intestinal auto-intoxication are of reflex origin. Many years ago Beaumont produced vertigo in the case of the Canadian trapper by touching the mucous membrane of the stomach. In this connection may be mentioned the large class of cases of idiosyncrasy to articles of food, *e.g.*, strawberries. The physiologist Ludwig is quoted to have said to his physician: "The intestines have a brain of their own, which is different in different individuals." In regard to the new intestinal antiseptics, there is more to be feared from the commercial invasion than from the bacterial one. The good results obtained by the author of the paper, Dr. Louria attributed to the large amount of water (two qts.), which the patients were compelled to drink daily. In order to diminish the odor of the stools, large enemata are far more effective than intestinal antiseptics.

BRITISH MEDICAL ASSOCIATION.[1]

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

(Continued from Page 480.)

Trypanosomiasis.—An extended discussion on this subject was held. Dr. David Bruce, in opening the discussion, reverted to the conclusions arrived at at the last meeting of the Association. These were: (1) That the trypanosome found in the blood of natives on the West Coast of Africa was different from that found in cases of sleeping sickness, and that, therefore, human trypanosomiasis and sleeping sickness were distinct diseases. (2) At this time last year it was considered that the native is immune to trypanosomiasis, but that the European is not, this conclusion being arrived at on the analogy of the wild and domestic animals and nagana. (3) A year ago it was held that the prognosis of trypanosomiasis in the native was apparently good; in the European it was not favorable, but certainly not necessarily bad. (4) At that time it was stated that the treatment of this disease so far had proved absolutely unsuccessful. (5) Another conclusion that was arrived at this time last year was that the trypanosome of sleeping sickness had other hosts in addition to man, and that the humbler mammals had probably a great deal to do with the endemicity of trypanosomiasis.

He thought that a great advance in knowledge of this subject had been gained during the last year. Only one of the conclusions laid down at the last meeting of this Association can now be considered to be correct. Of the propositions laid down at this meeting last year, about 80 per cent. of them are now shown to be incorrect. He hoped that this year's conclusions would not show a high rate of mortality.

The first proposition he laid down was that the trypanosoma found in the blood of natives on the West Coast of Africa and in Uganda, and those found in cases of sleeping sickness, are identical. The work on this subject has been mainly done by Laveran and Mesnil, by Dr. Thomas, of the Liverpool School of Tropical Medicine, and by the Royal Society Commission in Uganda. All have come to the conclusion that, morphologically, these trypanosomes could not be said to differ, and that their behavior when injected into various animals, was also identical. From these considerations, therefore, it is thought that the *Trypanosoma gambiense* (Dutton), found in the blood of natives in West Africa and the trypanosome found in sleeping sickness, are identical.

Trypanosoma Fever.—2. The next proposition laid down was that the so-called "trypanosoma fever" is nothing but the first stage of sleeping sickness. The chief proof of this is that several of the natives found with trypanosomes in their blood a year ago in Uganda, who appeared perfectly healthy and were going about their ordinary work without showing any symptoms of sleeping sickness, have now succumbed, or show decided

1 From advance sheets of the *British Medical Journal*, by courtesy of the editors.

symptoms of that disease. Captain Greig, of the Indian Medical Service, and Lieutenant Gray, Royal Army Medical Corps, who are still working at sleeping sickness in Uganda, have again examined as many of these natives as possible, and have found that many of them have died of sleeping sickness. Again, there were in Entebbe some five natives with trypanosomes in their blood who were kept under close observation. One of these natives is now suffering from unmistakable symptoms of sleeping sickness. From these facts, therefore, it is inferred that the so-called "trypanosoma fever" is nothing but the first stage of sleeping sickness.

Europeans Not Immune.—3. The next proposition is that neither the native nor the European is immune to this disease. If it is true that human trypanosomiasis and sleeping sickness are identical diseases, then this argument need not be pushed, as all are aware that very many thousands of natives have succumbed to sleeping sickness during the last few years. A short time ago it was also asserted that the European was immune to sleeping sickness; this, of course, like many another loose statement of the same kind, is now proved to be wrong, as several cases of this disease have occurred among Europeans.

Mortality 100 Per Cent.—4. The next proposition is that as regards prognosis, instead of being favorable, the mortality is 100 per cent. in both colored and uncolored races; at the same time it may be proved later that some of the natives—at least a certain percentage of them—who have trypanosomes in their blood, may kill off these trypanosomes before the disease has given rise to the pathological changes which constitute sleeping sickness. Greig and Gray in Uganda will have an opportunity of putting this to the proof, when they have examined all the natives examined for trypanosomes at this time last year. In his opinion, however, he doubted very much if man ever kills off the trypanosome when once it has gained entrance to the circulation. The incubation period may last for years, but he thought in all probability it will be found sooner or later that the man dies of the infection.

Lower Animals Immune.—5. The next proposition was that up to the present no evidence has been brought forward to show that any of the lower animals take any important part in the spread of human trypanosomiasis. This is a point upon which in all probability more light will be thrown within the next few years. There is no evidence, at present, that any of the lower animals take any part in the spread of the disease. It is quite true that many mammals besides man are capable of being infected artificially by this disease, and it is quite possible that this infection may take place sometimes under natural conditions, but when one thinks of the enormous number of infected natives in the sleeping sickness area, it is evident that there is no need to call in the aid of any of the lower animals to assist in the spread of the disease. Statements have been made that perhaps the trypanosomes live in the blood of fresh-water fish in the Victoria Nyanza. These fish are supposed to lie on the surface of the water, and some blood-sucking insect conveys the trypanosomes from the fish to the human subject. Others speculated in the same way as to the crocodile—which is very numerous in Lake Victoria—playing a part in the dissemination of this disease. These are most ridiculous speculations, and are not worth a moment's consideration.

A Fly the Infecting Agent.—6. The next proposition is that human trypanosomiasis is conveyed from the sick to the healthy by means of a biting fly—the *Glossina palpalis*. No evidence is as yet forthcoming from the West Coast of Africa in regard to the truth of this statement. He believes, on the West Coast, Dutton and others have found it impossible, up to the present time, to prove that there is any connection with the spread of this disease and the *Glossina palpalis*, but he thought the evidence brought forward in Uganda is overwhelming in this respect. The distribution of this disease was found to be most peculiar. Shortly, the disease was confined to a narrow strip of land running along the shore of the lake and to the many islands which dot the northern part of the lake. It was thought that this peculiar distribution must depend upon some peculiar factor, and that factor was found in the *Glossina palpalis*. The distribution of this fly and the distribution of sleeping sickness was found to be identical; where none of these flies existed there was no sleeping sickness. The evidence, then, in Uganda, was so strong that he had no hesitation in asserting that sleeping sickness was conveyed, at least in Uganda, by that species of tsetse fly known as *Glossina palpalis*.

7. It has, however, been proved that several members of this genus are also able to convey the virus from the sick to the healthy, and this constitutes a danger that this disease may spread into the British East African and other tsetse fly zones. The proof of the truth of this has been brought forward by Dr. Wiggins, of Nairobi, in British East Africa, who experimented with the three species of tsetse flies found in that locality. *Glossina palpalis* is not only able to convey the trypanosome of sleeping sickness from the sick to the healthy, but it is also able to convey the trypanosome of nagana, or a disease found in part of Uganda, which must be very closely related to nagana. If the *Glossina palpalis*, then, can carry more than one species of trypanosome, it is reasonable to believe that the other species of this genus will also be able to carry the infection of sleeping sickness. This then constitutes a real danger that this disease may become imported into British East Africa and spread southward and northward along the tsetse fly belts of the coast and large river valleys.

8. Although there is proof that the various species of the genus *Glossina* can convey this trypanosome, there is no proof that other genera of biting flies, such as *Stomoxys and Tabanus* carry the infection under natural conditions. The arguments for the proof of this proposition are that Nuttall, of Cambridge, who experimented on the conveyance of the nagana trypanosome from sick to healthy animals by means of *Stomoxys calcitrans*, always had negative results. Greig and Gray have tried this experiment in Uganda, with *Stomoxys*, and have also failed. Experiments on a huge scale have been going on in South Africa for many years in regard to the spread of nagana or the tsetse fly disease; it is only where the tsetse fly, *Glossina morsitans*, or one of its allied species, *Glossina palipides*, is found that this disease occurs. Outside that area there may be many other species of biting flies, but the disease never spreads beyond the zone of the tsetse fly. When in Africa he lived for two years on the top of a hill in Zululand, within a few miles of the fly country. He had many animals affected by tsetse fly disease living on the top of this hill and surrounded by healthy animals, but in no case was the disease conveyed from one of these sick animals to a healthy one, although there were numerous species of biting flies, other than the tsetse fly, to be found on the top of the hill. It has been said by Rogers that *Tabanus* can carry the trypanosome of surra; this may be true, but he must say that he had not been quite convinced that this experiment was carried out under the best conditions. It seems evident, if one places two animals beside each other, one affected with surra and the other healthy, if one proceeded to shave the skin of both these animals, thereby causing a great deal of excoriation of epidermis and the infliction of

small wounds; if one then takes a cage containing *Tabanidæ*, and allows them to bite the affected animal, and while so biting to suddenly have the cage transferred to the healthy one, is, to his mind, not a fair experiment; it stands to reason that any kind of biting fly would under these circumstances convey the infection to the small wounds and excoriated places which have been caused by the shaving.

Direct Infection.—9. There is no proof that *Trypanosoma gambiense* passes through any metamorphosis in *Glossina palpalis*, but that the transference of the parasites by this fly from one animal to another is purely mechanical. It has been said that the trypanosome undergoes a metamorphosis in the interior of the tsetse fly analagous to the metamorphosis which the malarial parasite passes through in the mosquito. The arguments in favor of the trypanosome being conveyed by the tsetse fly without any metamorphosis are: First, the fact that the fly is not able to retain, or does not retain, its infective quality for more than forty-eight hours. No one has been able to infect a healthy animal by means of the tsetse fly for a longer period than forty-eight hours, and his many attempts to convey the disease by means of the tsetse fly, three days after the fly had fed on trypanosoma blood, had always failed. If any metamorphosis analogous to that which the malarial parasite undergoes in the mosquito was undergone by the trypanosome in the tsetse fly, then it would be expected that the tsetse fly would not become infective until some time had elapsed from the last time of feeding; the mosquito in yellow fever does not become infected for some twelve days, and in the same way the mosquito in malaria takes some days before it becomes infected. After the work of Schaudinn on *Halteridium*, it would be rash to say that no metamorphosis or development takes place in the interior of the tsetse fly. In all probability some development does take place, but he asserted that this development will be found to be quite a different thing from the metamorphosis which has been prophesied, and which takes place in the case of the malarial parasite and the mosquito.

10. The present evidence goes to show that all the stages of the development of the *Trypanosoma gambiense* take place in the human host.

11. In regard to measures for the prevention of the spread of sleeping sickness: These should aim at preventing, as far as possible, the movement of natives from sleeping sickness areas into any part of the country where any species of tsetse fly is found. It was lately proposed to remove the Indian laborers from the British East African Railway and to replace them by native laborers from Uganda. One can easily imagine how dangerous such a course might be. Many of these Uganda natives might have the trypanosomes of sleeping sickness in their blood, and so convey that parasite into the tsetse fly district of British East Africa, and spread the disease to the natives of that part. Other measures would be the prevention, as far as possible, of the movement of healthy natives into sleeping sickness areas; the evacuation, if possible, of those areas; the destruction of the breeding places of the tsetse fly, and of the fly itself, whenever possible.

(To be Continued.)

Surgical Treatment of Chronic Bright's from the Ophthalmic Standpoint.—It has for some time been a recognized fact that patients, who suffer from chronic nephritis and show changes in the retina resulting from that disease, seldom live longer than two years. This ocular lesion, therefore, at once becomes a very important prognostic factor and it seems strange that surgeons contemplating the operation of decapsulation should so frequently fail to even look for this sign. G. F. Suker (*N. Y. Med. Jour.*, June 4, 1904) has carefully examined all the clinical data obtainable and finds that only 16 cases of decapsulation have occurred upon patients, undoubtedly suffering from albuminuric retinitis. These changes in the retina are simply evidences of irreparable inflammatory changes occurring not only in the eye but also in the kidney and throughout the cardiovascular system. Of these 16 cases not one lived two years, and the majority lived less than six months. It would seem proper, therefore, to say that the presence of retinitis contraindicates the operation of decapsulation. Since this ocular complication occurs in at least 25 per cent. of all cases of chronic Bright's disease, it is a sign which should always be looked for before such an operation is advised.

BOOK REVIEWS.

Surgical Differentials. By J. W. Draper Maury, M.D., Rockefeller Institute Research; Fellow in the Laboratory of Experimental Surgery, Columbia University, New York. Illustrated. James T. Dougherty, New York.

There are three distinctive characteristics to this little book: Differential tables, unique illustrations and an up-to-date, terse text.

Differential diagnosis has always been a difficult subject for every one. A volume which presents a long series of differentials in tabular form must therefore be useful. When, in addition, the tables are thoroughly correlated with the rest of the book, and all is made to follow a logical scheme, it becomes doubly valuable, for recitation purposes.

A book written to fill the vacancy for which this one has been designed is a distinct step in advance, when it places into the hands of students graphic "line sketches," made by one of themselves and so simple that any one can reproduce them.

The text is as clear as the illustrations, and reflects the most recent surgical advances, some of which have not yet found their way into general surgeries. The author strives to render his pages of value, particularly to the student who is preparing to take the competitive examinations for the hospitals. To this end he has, in addition, appended a list of the examinations for 1902 and 1904, at all the important hospitals in and near New York.

The book is well designed and in every respect a credit both to its author and publisher.

A Text-Book of Mechano-therapy. (Massage and Medical Gymnastics.) By Axel V. Grafstrom, B.S., M.D. Second Edition, revised and enlarged. W. B. Saunders & Company, Philadelphia, New York and London.

This popular little work appears in its second edition with two new chapters added, one on massage of the eye, ear, nose, and throat, and the other on pelvic massage. The aim of the author has been to make the work a rational text-book for the medical student, the trained nurse, and the medical gymnast, and also a reference work on the subject for the physician. The system practised by the Royal Gymnastic Institute in Stockholm, Sweden, has been principally followed, with such modifications as are recommended by other authorities. The book is simply, but quite completely illustrated. The increasing importance of this subject, makes this little work a valuable addition to the physician's armamentarium.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 85. NEW YORK, SATURDAY, SEPTEMBER 17, 1904. No. 12.

ORIGINAL ARTICLES.

POLYURIA IN TYPHOID FEVER.[1]

BY M. H. FUSSELL, M.D.,
H. S. CARMANY, M.D.,
AND
H. HUDSON, M.D.,
OF PHILADELPHIA.

MURCHISON, in his chapter on typhoid fever, says the quantity of urine during the first week or ten days is usually diminished. Sometimes it falls to one-half, to one-quarter, or even to one-sixth of the normal standard, notwithstanding the increase of fluid ingesta. After the second week the quantity increases, and he has frequently observed the urine to be copious, pale and of low specific gravity, before the cessation of the fever. But in most cases the quantity does not increase greatly until convalescence, when the urine is almost invariably copious and of low specific gravity. At this period he has repeatedly known as many as eighty or ninety fluid ounces passed in the twenty-four hours.

Arnould, in *Dictionaire des Sciences Medicales*, says the quantity of urine is almost always diminished, sometimes it is more abundant, and there may be a veritable polyuria; this may be a symptom preceding the defervescence. During convalescence the urine may vary between 1,500 c.c. in moderate forms of fever, and 1,700 c.c. in severe forms; this polyuria coincides with the more abundant excretion of the solid material of the urine. There is intimate relation between the function of the kidneys and the skin. When the patient is convalescent the polyuria corresponds with the abundant sweats; on the contrary, a dry skin and diminution of the urine is a grave sign.

One of the latest expressions on this subject is by Olser, who says: "An unusual increase of urine during the progress of convalescence is by no means a rare manifestation, so that the amount may reach 10,000 c.c. and more, in twenty-four hours. The urine is then remarkably light, as clear as water, and of exceedingly low specific gravity down to 1,002. Rarely, and then especially in nervous persons, women as well as men, this polyuria may be apparent as early as the latter portion of the febrile period."

Practically all authors of text-books are satisfied with the remark that the urine is scanty and of high specific gravity during the height of the fever, and more abundant, and of lower specific gravity toward and during convalescence. Some authors say that a convalescence can be practically foretold by an increase in the amount of urine of low specific gravity.

Under the caption, "Polyuria in Typhoid Fever," we could discover only one article, though isolated cases have been reported and not published. Dr. J. C. Wilson, of Philadelphia, reported a case of polyuria in typhoid fever at the Section of Medicine of the College of Physicians of Philadelphia, and will speak of his case in connection with this paper.

Spitz reported in 1882, under the caption, "Polyuria in Typhoid Fever," a case in a patient who had a severe attack of typhoid, who passed 6,000 to 8,000 c.c. of urine daily during convalescence. After this observation he had the daily amount of urine of all cases of typhoid fever measured, and it was found that in about one-half of the cases, polyuria was present in convalescence, he considering anything over 2,000 c.c. as a polyuria. The urine was always bright yellow, free from albumin and sugar and without any sediment; it was of low specific gravity, so that it consisted mainly of water.

He concludes: (1) In convalescence of typhoid fever polyuria is present in one-half of the cases; (2) the amount of urine may be increased by artificial means during severe high temperatures; (3) the increase of the amount of urine is most common in the sixth week; (4) the increase in the amount of urine is not due to any organic disease.

The case which we desire to report is as follows:

Case.—Charles S., married, aged forty years, admitted to St. Timothy's Hospital April 15, 1903, on about the eighth day of typhoid fever. The temperatures on admission was 103° F. It remained between 102° and 103° F. until May 4, when convalescence began.

On May 8 the temperature was normal and remained so until his discharge from the hospital. He was extremely nervous through the entire course of the disease. On April 23, eight days after admission, he had a slight intestinal hemorrhage which had apparently no effect on the course of the disease. He was taking five grains of salol every three hours on admission, and continued this drug until April 19 (four days), when it was stopped. The first twenty-four hours after admission he passed about 1,200 c.c. of urine. The second twenty-four hours he passed about the same amount. On April 18, or the third day after admission, he passed seven quarts and nine ounces (7,000 c.c.). The next day, seven quarts and eighteen ounces (7,200 c.c.). During this period he was nervous, but not so markedly as later, when he was passing much less urine; he was extremely thirsty, and drank water every

[1] Read before the Association of American Physicians, Washington, D. C., May 10, 1904.

few minutes, and passed his urine at very short intervals, in amounts varying from ten to twelve ounces. At this time the polyuria amounted to a veritable complication, on account of the loss of rest and the nervous excitement which it entailed. His skin was dry, and he was restless. He drank much water after the polyuria began. It was not measured. As the polyuria diminished the thirst became less marked; the increased consumption of water appeared to be the result, rather than the cause of the polyuria.

On the following day (April 20), the urine dropped to about four quarts, and remained between three and four quarts (3,000 to 4,000 c.c.) for two days. In the next ten days he passed between two and three quarts in twenty-four hours, and passed about the normal amount on May 13, or almost one month after his admission to the hospital. During this period, April 15 until May 6, his temperature ranged between 104° three quarts the specific gravity rose to 1,010, and remained at about 1,010 until convalescence was fully established. At no time was there any albumin or sugar or at any time were there any formed elements. On April 11, 1904, one year after the typhoid fever, an examination of the urine was made and it was found to be absolutely normal. He is in perfect health. On three days, April 23, 24, 25, 1904, he passed respectively, 41½, 41¾ and 43½ fluid ounces of urine. On April 26, 27, 1904 (that is, just one year after his attack), he was given five grains of salol every three hours, and passed on each day 54 ounces and 52 ounces respectively, specific gravity 1,026—otherwise negative, containing 2 per cent. urea.

On reviewing this case it will be seen that it differs from practically all of the cases of polyuria in typhoid fever mentioned by writers, in the fact that the polyuria began suddenly in the second week of the disease, and that the urine was

Fig. 1.

The dotted line represents the amount of urine, the solid line the temperature of patient.

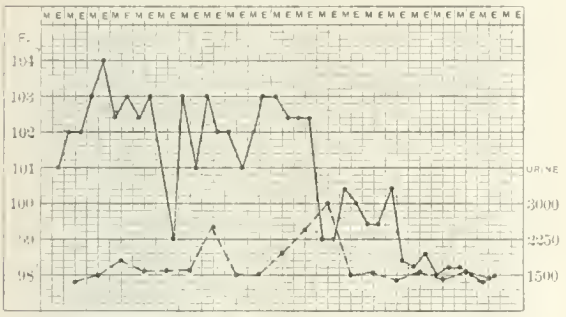
F., and normal, but during the greater part of the period was not below 102° F., except as the result of sponges. From May 6 to 14, when his temperature was normal, he passed between two and three quarts of urine daily.

It will be seen, then, Fig. 1, that during the height of the fever he had a veritable polyuria, and as the temperature reached normal he passed decidedly *less* urine. When his polyuria was most extreme the urine had a specific gravity of 1,002. On the first day it contained a trace of salicylic acid, as shown by the iron test, but only on that day; it contained neither albumin nor sugar, no acetone, and no diacetic acid, there was .004 grams of urea, to 1 c.c. of urine, or 4 per cent. He thus passed 28.8 grams of urea, which is not far from normal. As the specific gravity rose and the quantity of urea decreased, the urea percentage rose; he thus at all times passed about a normal percentage of urea. When the amount of his urine fell to greatest in amount during the height of the fever, and declined as convalescence began, and when convalescence was established the urine was absolutely normal in quantity and in character.

The polyuria spoken of by authors occurs just before, or during convalescence. In order to compare the amount of urine passed in this case with the amount passed in the ordinary case of typhoid, we have selected two cases of typhoid in which the urine was measured daily. In the patient (Ed. Dowling), chart 3, where daily measurement was made for four weeks, the urine never rose above 62 ounces in the twenty-four hours, and was often as low as twelve ounces. In only one other patient beside the one quoted in this series of 180 cases was there any excessive amount of urine passed during the height of the fever, and in that case it did not rise above 3,000 c.c., chart 2, in twenty-four hours. The amounts passed in this case will be seen by the chart, together with the range of temperature.

We have gone over the records of a series of cases in St. Timothy's Hospital with a view of proving the frequency with which polyuria occurred during the course, or in the convalescence of typhoid fever, and in 180 cases in which the urine was measured every day, we have discovered only 22 in which the urine was 2,000 c.c. or over, and in only one of these, the one above reported, was the polyuria constant from the beginning of the disease, and in no other case except this was there a very excessive amount, 3,000 c.c. being the limit.

Fig. 2.



The dotted line represents the amount of urine, the solid line the temperature of patient.

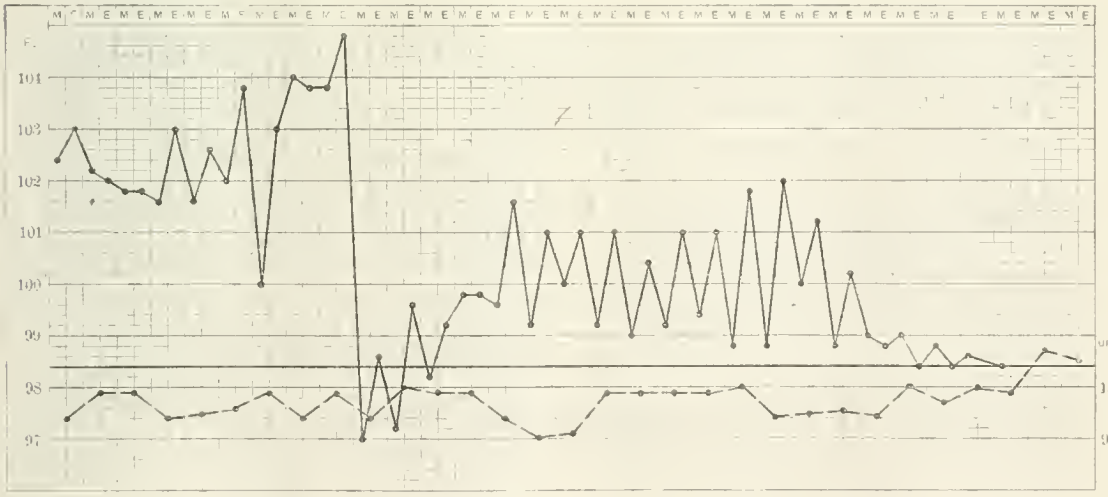
In the great majority of the cases it was scanty during the height of the fever, and rose only during convalescence; if, therefore, this series is reliable, and the measurements were made without any thought of the subject of polyuria, it would seem that the incidence of polyuria in convalescence is not nearly as common as most writers think, only eight per cent. of our cases showed a polyuria at any time, instead of 50 per cent., as Spitz has stated in his paper, or instead of being almost without exception in convalescence, as stated by Murchison.

As to the cause of the polyuria existing in this most remarkable case which we have reported, it was certainly not due to a pre-existing diabetes on admission, as for two days the amount of urine was normal, it fell to normal with convalescence, and has probably remained so ever since, as it certainly is as stated above at the present writing. It was not due to any organic condition of the kidneys, because the urine has always been, even during the existence of the passage of a great amount, normal so far as albumin and formed elements are concerned.

There would seem to remain of the ordinary causes of polyuria but two, the administration of salol, and the nervous condition of the patient. The salol was stopped on the second day of polyuria, but the abnormal amount of urine continued for almost one month after the discontinuance of the drug. It seems scarcely possible, therefore, that the salol could have been the causative factor. The patient was nervous, it is true, but when he was passing the greatest amount of urine he was much less nervous, than later when he was passing from three to four quarts.

The patient was not given the bath treatment. He was under treatment in a private room, and by direction of his physician was sponged at the temperature of 103 F. or over. It is quite within the range of possibility that these cold sponges may have had something to do with the polyuria, but it seems scarcely possible, because he received eleven sponges before the polyuria developed, and the condition continued eleven days after the sponges were stopped, although in gradually diminishing amount.

Fig. 3.



The dotted line represents the amount of urine, the solid line the temperature of patient.

As to the cause of polyuria in general this paper cannot deal. The most common causes given by authorities, however, are nervousness and some organic change, either in the nervous system, or in the kidneys themselves. Certainly the last two were not active in this case, and it would seem that the unusual amount of urine

was caused either by the very moderate use of cold water, or by the unusual and continued nervous, almost hysterical, condition of the patient.

We conclude: (1) That the urine during the course of typhoid fever is usually of high specific gravity and in amount below 1,500 c.c. in twenty-four hours. (2) In convalescence the amount of urine may rise in a small percentage of cases to 2,000, or even to 10,000 c.c. in twenty-four hours. (3) That in very rare cases there may be at times polyuria of from 3,000 to 8,000 c.c. in the twenty-four hours during the entire course of the disease.

TREATMENT OF ACUTE MIDDLE-EAR DISEASE.[1]

BY JOHN A. DONOVAN, M.D.,

OF BUTTE, MONTANA.

If it were not for the constant demand on every physician, specialist or not, to treat this most common disease, the great suffering of the patient and the bad sequelæ so frequently occurring from its nearly equally common mistreatment or neglect, I would not have selected this subject.

I omit its general pathology, assuming you are already familiar with it. Acute otitis (I will make no anatomical classifications) occurs most frequently in children, and nearly always follows some irritated condition of nasal pharynx; of these, the earliest and most common is adenoids, which should be looked for in all cases. The most simple method of examination is by using the finger; with the inexperienced, any method may fail to show the smaller growths, the most frequent but none the less annoying. If any ear or catarrhal symptom exists, the thorough removal of even the smallest adenoid tissue should be insisted on.

Every operator has his preferable method. I prefer the curet, finger nail, or nail curet. As to anesthetic, chloroform is extremely dangerous. I have on several occasions been obliged to resuscitate patients and operate after they have regained consciousness. This has occurred when the most careful physicians were giving the anesthetic, and every precaution taken. Ether is safer, or better still, some of the quicker ones, *e.g.*, nitrous oxide, etc. In infants and young children, adenoids can be thoroughly removed so rapidly that general anesthesia is hardly necessary, and there is almost no pain afterward. In older children and adults, cocaine may be used; in fact, a single application of 5 per cent. in young children may be safely used, and lessens the pain. In every case, thorough work is essential for the best results.

The next most frequent cause, and a condition usually accompanying this, is enlarged tonsils. They should be entirely removed, or as much removed as possible. This is only accompanied by seizing the tonsil with a good forcep (after trying many, I prefer Peter's), then, after separating the pillars, cut off with scissors, snare or tonsillotome. For this cocaine is safer, but many patients resent the combined operation without general anesthesia.

After these are the acute diseases, as scarlet fever, diphtheria, measles, etc. In measles, according to Bezold, the middle ear is injected early; post-mortems demonstrated this condition in many cases, with no symptoms observed in life. Quoting from Dr. D. T. Vail's paper, he says: "It is claimed, 4 per cent. of deafness is due to measles."

Scarlet fever is very commonly accompanied, and followed, by acute purulent otitis. It is more profound than that of measles, and more likely to bone necrosis, cranial complications, general septicemia and death, or permanent impairment of hearing. The same author states 19 per cent. of deaf mutes owe their condition to this cause.

In diphtheria, it is quite frequent, but hardly as severe. Influenza is sometimes accompanied by small hemorrhagic bullæ on upper part of drum, which rupture early. Suppuration and mastoid abscess is very common during epidemics of this disease. Other causes are brain disease, typhus, smallpox, chickenpox, erysipelas, whooping-cough, mumps, pneumonia, rickets, tuberculosis, syphilis, etc. The multiple perforation in early stages of tuberculous diseases is a decided aid in its diagnosis.

Having already mentioned the prophylactic treatment in adenoid conditions, it must not be overlooked in these other diseases, but more especially scarlatina, measles and diphtheria. In each of these, and in fact in any inflamed condition of the nasopharynx, a mild antiseptic wash would prevent many of the disagreeable accompaniments of the disease, and avoid many cases of otitis. In fact, R. E. Lander, of Southampton, England, after a vast range of experience with scarlet fever, reports in the *Lancet*, March 12, facts that make us believe our long-cherished dream of the contagious scales is about to vanish, for of patients leaving in two weeks, having had noses and throats made clean, the return cases were very much fewer than occurred from those who were retained till desquamation was complete.

As to the solution, a mixture of equal parts of borax, salt and soda, a teaspoonful to a pint of warm water, is very useful. This may be improved by adding six drams of glycerin, and if required to be more germicidal, formalin, say four to eight drops (the glycerin prevents its irritating action). To this, menthol, thymol, etc., may be added as desired, but pharmacists usually do not succeed in mixing them satisfactorily. These essential qualities are combined in thymo-glycerin compound or Pynchon's Dobel solution, which, when diluted, one ounce to the pint, gives a solution somewhat similar to the above, combining the therapeutic and antiseptic effect of menthol and thymol. Glyco-thymolin, borolyptol, listerine and other similar preparations are all useful, and it becomes largely a matter of individual choice. The formula given contains alka-

[1] Read before the Montana State Medical Association, Butte, Mont., May 18, 1904.

line salts in about the same proportion, and has a specific gravity much similar to blood serum when diluted.

As to the method of use, a simple glass douche is convenient, but ear diseases may follow it, though with proper care this should not occur. Putting not over a teaspoonful in the hand and snuffing it up is probably the safest, but it is difficult to get children to do this. When this is done by first holding the hand two or three feet from the floor, stooping to draw it up, then while still holding the nose in the hand and, raising the head, allowing the fluid to flow back to the pharynx, complete cleansing is accomplished. In children, it may be put into the nostrils by saturating cotton, then squeezing it, or with a dropper or spoon.

An atomizer, possibly, is the more likely to be used. Unfortunately, since the poorest atomizers are retailed at about the price of the best, and at much larger profit, the patient not being able to select, usually gets an inferior one. The De Vilbiss No. 16 and Century Nos. 10 and 50 have two bottles, and use oil and water, both always at hand. The De Vilbiss throws a spray or stream, as desired, in any direction, has metal trimmings, and is therefore easily cleaned. The Whitall Tatum, Nos. 30 and 33, have given me good satisfaction, also. The first two firms, and I think any first-class makers, will replace any defective goods. The physician should select one or more good ones, and stick to them, as patients never appreciate prescriptions for ones that do not work. The druggist does not care to carry great varieties of perishable rubber goods, therefore he should be informed of your choice.

Usually the first manifest symptom of acute otitis is pain. In infants, this is frequently overlooked; many develop meningitis before it is suspected. All infants should be carefully watched for manifest signs of earache. In adults, a diagnosis is easily made. Active treatment consists of relieving pain, endeavoring to avoid suppuration and other complications. Heat is the first remedy.

I advise a large fountain syringe filled with water as hot as can be borne, held about three to six inches above the ear, the water flowing into the ear through a return-flow ear douche emptying into a basin. The canal is then dried and filled with phenol, m. 50; glycerin, 1 oz., which is left in. This should be repeated every two to six hours, according to amout of pain. Take cocaine hyd., grs. 6 to 10; absolute alcohol, drams 1; aniline pure, drams 1; four or five drops in ear, repeated each hour till pain is relieved, is more effective, but much more dangerous. Both have a dehydrating action, which is much to be desired. Dr. Richards gives a formulæ: take phenol, m. 7; F. E. opii, m. 6; cocaine, grs. 3; atroph. sulph., grs. 3; aqua, m. 52; gelatin, grs. 18; glycerin, m. 158; M. S. Make 42 bougies. These have the advantage of convenience, safety, permanency and efficiency.

When pain persists after twelve to twenty-four hours of such treatment, I employ drainage. Formerly, I made free incision at this time into the drum, opening it from bottom upward very freely. For this, the cocaine, aniline oil and alcohol preparation is useful, but nearly always considerable pain persists.

Since selecting the title of this paper, I have in several cases used a method advised by Hazen in his little book, "New Findings," *i.e.*, the Eustachian catheter. He claims that the return flow of air carries out fluid secretions and relieves congestion. I use air hot as can be borne through the catheter, and in the few cases so far, results have been very gratifying. The Politzer method of inflation is injurious in this condition. After free incision has been made, the canal, having previously been cleaned, is now lightly packed with sterilized gauze, loose enough to afford drainage. If the opening has been made the first or second day, the discharge is likely serious, and an effort is made to keep it so, by free drainage and avoiding infection. Outside this gauze in the canal is placed a large gauze or cotton pad, sufficient to absorb all discharge reaching it. This outer pad is changed whenever it becomes damp; that in the canal is left twenty-four hours.

If the operation be done within the first forty-eight hours, a few days to a week or two is usually all the time required for healing; if done later, the time is considerably lengthened. If mastoid trouble develops and continues after the ear drum is freely opened, the bone should be opened. Free opening into the antrum and removal of all diseased bone, wherever found, under careful inspection in good light, should always be done. Follow the diseased tissue everywhere, irrespective of its location and dangers. Deaths from neglect to do this far exceed the possibilities of accidents in operating.

Conclusions.—1. In all diseases affecting the nasopharynx, always use reasonable precautions to avoid tubal infections.

2. Adenoid tissue, in any amount, and tonsils producing any pathological symptoms, should always be removed.

3. With the first symptoms of earache, use heat and dehydrating remedies; this not producing beneficial results in a few hours, treat surgically.

4. When possible, with a catheter use mild continuous stream of hot air early, and repeat in eight or ten hours.

5. If symptoms are not relieved by these methods within ten to twenty-four hours, make free incision through the entire drum, or extend into upper canal wall if necessary. Use aseptic gauze drainage and outside pad for absorption.

6. Never under any conditions allow the patient to suffer tortures for more than forty-eight hours and remain exposed to the risks of complications.

N. B.—Considerable experience with the catheter treatment, since writing the above, fully confirms the original hopeful anticipations, and has very much lessened the number of cases requiring opening of the drum.

THE VALUE OF EARLY INCISION OF THE MEMBRANA TYMPANI IN THE TREATMENT OF ACUTE SUPPURATION OF THE MIDDLE EAR.[1]

BY FRANCIS R. PACKARD, M.D.,
OF PHILADELPHIA;
PROFESSOR OF DISEASES OF THE EAR, PHILADELPHIA POLYCLINIC HOSPITAL; AURIST TO THE OUT-PATIENT DEPARTMENT OF THE PENNSYLVANIA HOSPITAL.

ALTHOUGH my subject may seem a somewhat hackneyed topic to venture upon before such an audience, I have chosen it for the reason that I believe wherever a man's personal experience has proved of value to himself it may also prove of some service to others.

In Philadelphia, during the months of February and March of the present year, there was a marked increase in the number of cases of acute suppurative otitis media, occurring in conjunction with attacks of grip. As is so often the case in epidemics of grip, the complications not only were of the same general character, in this instance, largely aural, but also presented certain very definite individual peculiarities. Thus, the suppurative process developed with great rapidity, as a rule the abscess pointed and ruptured within twelve or fourteen hours after the onset of the pain in the ear. The discharge which ensued was at first very scanty, usually blood-streaked, but soon became very profuse. The pain continued to be intense for some days after the rupture of the drum occurred, in spite of free drainage of the pus from the middle ear. It was always worse in the afternoon, the patient being comparatively comfortable until that time.

In many cases pointing of the abscess and spontaneous rupture of the drum membrane occurred with such rapidity that the patient was not seen until subsequent to the appearance of the discharge. The cases to which the writer would particularly draw your attention were all of them observed and treated by him personally throughout their course. There were other cases occurring in his hospital service which he did not have the opportunity to follow up so thoroughly, but from the reports of his assistants these bear out the statements made concerning the twelve cases which are here presented.

In seven instances in the author's experience in which spontaneous rupture occurred, the patient suffered much pain in the ear for many days after the rupture had happened, and the discharge continued in two instances as long as four weeks, and in the other five for periods varying between ten days and three weeks. In three cases, in which early incision was practised, there was almost instantaneous relief from pain, and the discharge had ceased, in one instance, at the end of three days, and in the other two at the end of five.

After the drum membrane had been opened, whether spontaneously or with the knife, the same plan of treatment was pursued in all twelve cases. This consisted in a thorough cleansing of the ear once daily by mopping out with peroxide of hydrogen, full strength, applied on cotton pledgets, followed when the discharge was very profuse by injecting a few small syringes full of bichloride of mercury 1 to 4,000 solution. After thoroughly drying, a wick of iodoform gauze was introduced throughout the whole length of the canal, and left in position until the next day, the nurse or patient being given instructions to remove it if there were any evidence of it damming up the pus. I believe that drainage procured by this method is the most efficient means of avoiding stagnation of the discharge, pain and mastoid involvement.

When the pain was very great at the time that the dressing was done, I found that great comfort was given the patient if after cleansing the ear and drying it, an anesthetic mixture consisting of five parts of a 10 per cent. solution of cocaine, combined with 50 parts of anilin oil, and 50 parts of 5 per cent. of alcohol was instilled. This was allowed to remain in the ear for a few moments and mopped out before the insertion of the gauze drain. In two instances in which this mixture was used the patients' temperatures became subnormal, and they were very deeply cyanosed, the blueness lasting for several days. As a case of death has been reported occurring from the use of this mixture, it should be employed with considerable caution. Both the author's cases recovered without further interference. The gauze drain not only afforded relief by drawing off the pus, but the patients all seem to experience a sense of comfort, apparently because, as they expressed it in several instances, "it kept the walls of the canal apart."

The cases which the author observed would seem to him to have emphasized the following points in the treatment of acute suppurative otitis media. First, the great value of early incision of the membrana tympani. Second, the many advantages possessed by the so-called dry treatment, and by practising efficient gauze drainage. I believe that douching out the ear by the patient or nurse is distinctly contraindicated from the fact that no one but a skilled aurist can properly dry the ear after such procedures, and that the little pool of fluid which is left is very harmful in that it affords moisture for the furtherance of bacterial growth.

[1] Read by title at the meeting of the American Laryngological, Rhinological and Otological Society, June, 1904.

Nitrogen Necessary for Life. The atmosphere is composed of a mixture of oxygen and nitrogen, the former substance being essential to life. It has been a matter of scientific speculation, however, what part is played by the nitrogen, and whether it could be supplanted by hydrogen. Professor Marcacci, of Palermo, Italy, has recently shown that in an atmosphere artificially constructed with an equal amount of hydrogen substituted for the nitrogen, that life cannot be supported for any length of time. Professor Marcacci tried to keep animals in such an atmosphere, but he found that they soon died, the same effects being noticed as would result from cold. This is explained by the fact that hydrogen possesses greater conductivity for heat than nitrogen.

CONTRIBUTIONS TO THE PATHOLOGY AND TREATMENT OF ACUTE GONORRHEA.

BY LUDWIG WEISS, M.D.,

OF NEW YORK,

PHYSICIAN TO THE GERMAN POLIKLINIC, SKIN [illegible] NARY DEPARTMENT; CONSULTING DERMATOLOGIST [illegible] ORPHAN ASYLUM, NEW YORK.

(Continued from Page 492.)

FORMERLY when the causative factor of gonorrhea was unknown, temporizing during the acute stage and suppression of the discharge by astringents formed the main aim of treatment. By dint of some presentment of an etiological cause, the antiseptic astringents, especially the nitrate of silver, were employed, and as we all know with excellent results. But its microbicidal action was at times superseded by its irritating astringent properties, which are undesirable in the acute stage. Klotz,[78] however, recently advocates retrograde injections of two per cent. solutions of nitrate of silver. The untimely use of astringents in the first stage of acute gonorrhea by retarding phagocytosis would frustrate Nature's endeavors to flood out the gonococci. Not the cessation of the discharge by astringents should be our aim at this period, but the dislodgement and possible annihilation of the gonococcus by microbicides. Hence the injunction of old writers not to suppress the discharge too quickly. Their fear of a "gonorrhea sicca" as causing systemic complications was founded on broad experience, and, as usual, an excellent observation. On the lines defined by Neisser, to treat gonorrhea on etiological principles only, can success be achieved in the strenuous battle against this loathsome disease. We may probably not succeed to attain absolutely what we strive for: the gonococcus may even under the etiological treatment with the new silver compounds occasionally invade the deeper tissues and give rise to latent processes and complications, but with no other mode of treatment will such an occurrence be less frequent than with the etiological treatment of gonorrhea.

In order to exclude the irritating and caustic effect of nitrate of silver without dispensing with its eminently bactericidal properties, there have been devised of late silver compounds, known as silver albuminates, containing silver in organic combinations. They have in common the property of not being precipitated by chlorides and albuminates in the secretions.

The first of the series was argonin, a silver casein compound, containing 1.2 per cent. of silver; next largin, a paranuclein proteid, with 11.1 per cent. of silver; followed by protargol, with 8.3 per cent. of silver, and argyrol, a silver vitellin produced from the proteid derived from wheat, with 30 per cent. of silver.

In another group of preparations, by combining the nitrate of silver with various substances combinations were produced in which the silver is contained in a form resembling a salt, and these among others are argentamine, with 10 per cent. albargin, a gelatose silver, with 23.6 per cent. ichthargon, ichthyol-sulphonic acid, with 50 per cent. nitrate of silver. Their virtues are extolled on different scores. For instance, in albargin the silver is loosely combined with the proteid, which I cannot regard as an advantage, as maintained by Bornemann,[79] as it is apt to be precipitated too soon, before coming in intimate contact with the mucous membrane.

Much importance is of late being attached by exploiters of some of these preparations as to their ability to dialyze, and from these laboratory experiments a higher penetrative power has been deduced. Their diffusibility through animal membranes—through dead ones—is correct; but the urethral mucosa is a living membrane, and a very active one. Haidenhain has conclusively shown that living mucous membranes do not permit of dialyzation or osmosis. My own investigations corroborate this point. Whether a preparation dialyzes or not through dead membranes in laboratory experiments makes no difference; nothing diffuses through living membranes. Not the slightest demonstrable trace of silver could be detected in the deep epithelial strata when experimenting with any of these preparations, so that in respect to penetrating power in the living mucous membrane, they stand alike, *i.e.*, nil.

The experiments made by Schaeffer with argentamine, by Benario[80] with protargol, by Aufrecht with ichthargan, and by Martin with argyrol, were all faulty in conception, and therefore useless. They used dead liver tissue, and not even dead urethral mucosa. Martin,[81] in order to show the penetrative power of argyrol, employed strands of catgut. From the more or less deep impregnation of these tissues they sought to prove the power of penetration of these remedies. Dr. Edwin C. Burnett,[82] at the Association of Genito-Urinary Surgeons, Washington, May 12, 1903, found in his experiments on the living urethras of dogs and rabbits, by using a 1 to 5 per cent. argyrol solution, that it penetrated only the upper surface of the top layer of cells. These correspond with the investigations carried on by me and Dr. Henry Kreuder, of New York, in the latter's laboratory, the results of which will be published in detail elsewhere.

The living cell will absorb crystalloids like iodide of potassium, but is impermeable to mineral or colloid substances, of which the silver salts are made. Neither does the fact so vividly emphasized by Neisser, that these preparations, because they are not precipitated by the normal tissue fluids, as is silver nitrate, secure for them the virtue of possessing penetrative power. Neither of these two physiochemical conditions enables them to be absorbed by the living membrane. Penetration in the living membrane takes place by absorption, in the dead tissue through imbibition.

As to the bactericidal and antiseptic power, laboratory experiments, although not exactly reproducing conditions as they exist in living tissues, are of somewhat more value. As to these

properties there are differences among them, as will be shown elsewhere.

On account of their large percentage of silver (23 to 30 per cent.) albargin, ichthargon, and argyrol, are said to possess a more pronounced germicidal power than the other silver albumin preparations. Metallic silver is inert. In its chemical combination with nitric acid it yields the well-known nitrate of silver, justly held in high estimation by everyone. Porosz[83] and others think its action due to the liberated nitric acid. But these new proteid silver preparations are devoid of any chemical formula. Their existential idea is based on the anticipated conclusion that in combining silver with a proteid body, more or less homogeneous to the tissues, such a combination will, thanks to its unirritating properties, permit of a longer contact with the tissues, and allow of a diffusion through the cell textures. The wish here is the father of the thought. In every instance where any of these newer silver preparations has been lauded a high penetrative power has been attributed to it. It seems to have been a foregone conclusion that because a combination is of only slightly alkaline reaction, and because it contains so much silver, and because it is combined with some of the many proteid derivatives, such a loose unchemical mixture will at once upset the laws of physiology by rendering living membranes permeable to colloids because in a laboratory experiment dialyzation through dead animal membranes has taken place. A high percentage of silver is no indication of a greater gonocidal power, since compounds weak in silver have proved as effective in eradicating the gonococcus as other silver combinations containing much larger amounts, and which are employed in strong solutions. A very unpleasant feature of argyrol is its staining effect, and not only for cosmetic reasons, but also for its telltale nature, which is an objectionable quality for a drug used in this "secret" disease.

In my service at the German Polyclinic I have made control experiments for the purpose of determining the comparative irritation between protargol, in one-half to three-quarters per cent. solution, and argyrol in two to five per cent. Although the patients were not apprised of our intentions they invariably complained of some irritation when argyrol was used in from two to five per cent. In both instances some sensations of irritation were complained of. My own observations as to the possibility of irritation from argyrol are confirmed by some references to this point in the literature. In two cases the patients brought small dark gelatinous masses looking like "liver," which they had voided when urinating. The injection with argyrol was made four hours before, and the patients had not urinated since. Examination of this mass revealed argyrol in a congealed condition. This was proven by dissolving it in distilled water and adding ammonium sulphide. A precipitate of silver sulphide took place promptly.

As to protargol, Neisser, on the strength of Benario's investigations[84] after previous extended trial in his clinic, published his first report in 1897.[85] His excellent results were soon confirmed. I have dwelt extensively at an earlier period on protargol medication in several communications,[86] and will not attempt here even to partially enumerate the enormous literature which has accumulated since then.

Protargol is certainly the best studied of all the antigonorrhoics, having stood the test of time and being most extensively employed; and having in the greatest majority of cases yielded the best results, one is justified in drawing definite conclusions regarding it. Under its use complications have been avoided in a larger number of cases than with other preparations of its kind. Already in my earlier communications I attributed some astringent properties to protargol which were doubted by Frank.[87] I have since found that in the stronger solutions it certainly exerts such an influence, and Grossglick[88] also presumes this to be the case. Since astringent properties are desirable only in the second stage of gonorrhea to diminish the discharge and to combat the lesions due to the gonococci, and as these stronger solutions, 1½ to 4 per cent., are used only in the defervescing period of the process, it will here act as an antiseptic astringent, a property of protargol that has not yet been referred to, and to which I would like to draw attention.

Individualization.—Writers on the treatment of gonorrhea usually impart the advice not to generalize, but to treat each case as befits its condition. But outside of generalities we are not told how to do this. This is due to the circumstance that the pathology of gonorrhea—autopsies being of extremely rare occurrence—does not explain the clinical symptoms precisely enough to indicate what should be done or left undone under certain special pathological conditions. Therefore a certain amount of generalization will always be necessary, and we will have to individualize as best we can. The following is but a modest endeavor of individualization which I am in the habit of pursuing.

1. *As to the General Health of the Patient.*—The natural power of defense and the degree of such power is variable in different individuals. The so-called diathesis, for want of a better expression, undoubtedly plays a great rôle in gonorrhea also. In the lymphatic, gouty, diabetic, and in those afflicted with syphilis the acute gonorrheal process may run a course of different grades of severity, but it will usually be of longer duration and more prone to complications than in those untainted. I think this to be due to defective leucocytosis as a manifestation of a weakened repelling power of the system. The leucocytes may be so altered in their chemical, and probably in their minutest, as yet unrecognized, histological composition, that they do not, as is normally the case, present suitable nutrient media to the gonococci. They will not ingulf them, and the gonococci, in a large proportion at least, re-

main free outside the cells. In the discharge of such patients we will observe certain peculiarities which may be conveniently subsummarized as follows:

Scanty discharge; poor in serum, proportionately well supplied with leucocytes, but gonococci mostly outside of them; or abundant discharge: rich in serum, poor in leucocytes, and gonococci also mostly outside; in both conditions the toxins which the gonococci elaborate will have been only partially neutralized by deficient phagocytosis. The progress of the gonococci having been thus only incompletely checked they will invade the deeper structures and, exerting their deleterious influence, will cause complications to occur near and remote. This deficient phagocytosis will promote also a permanency and longevity of the gonococci. Furthermore, we know that the gonococci elaborate toxins, that is, products of their own metabolism; these toxins are in part neutralized by the leucocytes, provided they are present in sufficient quality and quantity, and partly will these toxins serve to destroy the gonococci themselves. They are destined to perish by their own toxins. Such is the case when the discharge possesses necessary conquering qualities, but in debilitated subjects these conditions will be found more or less altered and the process prone to become systemic.

Our aim, therefore, will be to establish, by all available means, a satisfactory discharge, trying to promote a local leucocytosis. Attempts have been made by Dehio to create such in lupus patients by a subcutaneous injection of the proteins of the *Bacillus prodigiosus* and *Bacillus pyocyaneus*. The tuberculin and antistreptococcus serum, etc., are employed on this same principle. Even speculative pharmacy has philanthropically introduced preparations of nuclein and nucleo-albumins for this purpose, but without effect. If we get such a case with the above-mentioned characteristic microscopical evidences within thirty-six hours after exposure, abortive treatment should be tried at once. In this condition I prefer to use nitrate of silver, which by its irritative power gives the best chance for augmented leucocytosis. But if a patient of this class presents himself later than thirty-six hours, but not longer than four to eight days after exposure, I resort to what I call heroic, early treatment, which is somewhat akin to abortive efforts. I initiate the treatment by the use of a one per cent. protargol solution, every four hours, two syringefuls to be kept for five minutes each, with the purpose in view of utilizing the slightly irritating properties of such a concentration to establish a serviceable discharge. In addition I apply a wet-pack around the penis—gauze strips soaked in diluted Burow's solution, with rubber tissue and roller bandages—during the day; in the evening a hot sitz-bath, or, if this is impracticable, immersion of the penis several times, for ten minutes, in water as hot as can be borne, and the wet-pack over night. I advise a nourishing diet and permit even the moderate use of beer. Besides these modifications the customary injunctions are exacted: the wearing of a suspensory; no bodily exertions; sexual rest, etc. The intelligent use of the microscope, of the greatest utility in treating gonorrhea, is absolutely indispensable here. As soon as a discharge rich in bodily elements shows up, the treatment must be changed at once. Protargol may now be employed in only ¼ per cent. strength in the customary way. The wet-pack and hot immersion are left off, beer interdicted, and the usual mode of treatment pertaining to acute gonorrhea is resorted to.

2. *As to Local Manifestations.*—Already the older writers distinguished the irritable or arterial form, the phlegmonous, and the catarrhal or lymphatic form. In the light of modern pathological views we may call these peracute, acute, and subacute gonorrhea. Clinically these forms show different degrees of inflammation. There may be present a superficial or deep gonorrheal process, one that is localized in the fossa navicularis only or extends over the whole pendulous portion or to the bulbous also, or where the deeper tissues are involved. This is due to the different degrees of virulency of the etiological factor, to the different receptivity of the tissues so affected, and to the variety of the pathological lesions caused. This deviation in manner of the three factors may be sufficient to modify the symptom complex and the different grades of severity in different individuals. It is obvious, therefore, that we cannot look forward to a remedy which would cover all these conditions, unless we can cause the invaded soil to react uniformly to the invasion, or have the gonococcus possessed with a uniform degree of virulence in all cases.

While I am a firm believer in the antiseptic treatment in the first, or purulent, stage of acute gonorrhea, I am also convinced that astringents are contraindicated in this stage. Formerly gonorrhea was held to be only a catarrhal affection of different degrees of severity, and the discharge its main symptom to be combated. Consequently astringents were exclusively employed. In the light of the modern conception, which concedes to the leucocytes the power of elimination and neutralization of the invading parasite, we look to a certain extent upon the discharge as a highly essential ally. But in the second, or muco-purulent stage of gonorrhea, when the system has done its best eliminative work, when the surviving gonococci and their toxins are lessened in numbers and attenuated in their virulency, permitting milder clinical symptoms to prevail, in the so-called subacute stage, an astringent will be useful.

Peracute Gonorrhea.—The treatment of this form should be one of extreme conservatism. Despite the promodern views of immediate interference, the old adage "nil nocere" should here be our guide. In the presence of highly inflammatory local symptoms, such as pouting of the meatus, dorsal lymphangitis, balanitis, folliculitis, cavernitis, chordee, ardor urinæ, and profuse gonococci-bearing discharge, even bland injec-

tions, let alone irrigations, are extremely painful, harmful, and fraught with danger of complications and of systemic diffusion of the process. The organism itself, which reacts so heroically to the gonococcus invasion, shows plainly that it is well fitted to cope with it. It draws on its resources plentifully. A mighty repelling battle is being fought, and instead of blood, which is not a rare intermixture, the white discharge floods the battlefield. It fairly begs in mute eloquence to be left alone! Do we inundate a highly inflamed wound with irritating antiseptics? Let no fear of entertaining antiquated ideas deter us—the railroaders of gonorrhea notwithstanding—to institute antiphlogistic and expectant treatment. Rest in bed with elevation of the penis, application of Burow's solution, or liq. plumb. subacet. c. opio, with cold water wrappings around it; a saline aperient and alkaline mixture (citrate of potash or soda in sweetened lemonade, a dram to the pint, is a pleasant, cooling extempore beverage), a bland and semiliquid diet will tide us over until the most acute symptoms have subsided, and the process enters the stage which is clinically called acute gonorrhea.

I employ a syringe large enough to moderately balloon up the anterior urethra. I deplore overdistention. To choose a syringe of different sizes for each patient, according to the capacity of the individual urethra, as recommended lately, while desirable, is impracticable and meddlesome. As the average capacity of the male urethra, that is of its anterior portion from the orifice to the compressor muscle, is about one to two drams, I think it best to use a syringe which will hold four drams. This will answer the capacity of any urethra. In injecting the contents tentatively and with great precaution and not to the point of forcing the cut-off muscle, this surplus will expand the urethra, smooth out the folds, and so will bring the remedy in contact with the whole diseased surface. The syringe should have an olive pointed tip, made either of porcelain or glass, soft or hard rubber; the barrel should be of glass with hard rubber mounting. The piston should act easily without jerking. The injection should be a prolonged one, *i.e.*, be retained in the urethra from ten to thirty minutes. The original recommendation of Neisser was that two of these injections—morning and noon—should be retained for five minutes, and the third, or evening injection, for thirty minutes. We need not adhere to these directions too slavishly; the main aim is to get the gonocidal remedy into intimate and prolonged contact with the mucous membrane. Should the fingers which hold the orifice closed become tired, the fluid may be allowed to escape and another injection be made afterwards. This may be followed by a third one, each time allowing the solution to be retained for five minutes, at least. Or the patient may inject, if there is a very profuse discharge, six times a day (the more the better), retaining it for five minutes and longer if he can. Mechanical devices for keeping the solutions in the urethra without the aid of the compressing fingers have been invented, but have proven failures.

It is impossible to make an arbitrary distinction between the different clinical phases of the florid stage. The symptoms overlap each other or coalesce. But it is quite feasible by studying the condition of the discharge to determine whether the process is in the beginning or in the acme of the florid stage. The usual time distinction by days or weeks is untenable, because an uncertain quantity.

The beginning of the florid stage is characterized clinically, besides the different subjective symptoms of pricking or smarting during urination, by a reddened somewhat puffy meatus, a muco-purulent discharge of milky or yet slightly creamy pus filling the orifice or appearing in it on pressure, but not yet exuding from it. Microscopically the greatest number of gonococci are found on or upon pavement epithelium or free, and only a smaller number in leucocytes. This shows first that the process is yet a superficial one, and second, that it has not yet extended beyond the fossa navicularis. If a patient with such clinical symptoms and microscopical evidences applies for treatment, with the second portion of the urine clear, showing no involvement of the posterior urethra or the adnexa, I begin active treatment at once. The patient having urinated, I flush the first of the pendulous urethra with warm sterilized water, using for the purpose the large 150 gm. sterilizable piston syringe with interchangeable porcelain or soft rubber tips. To avoid carrying germs into uninfected parts the patient compresses his urethra firmly, in such a way that the index and second finger of the left hand compress the urethra upwards and the thumb placed on the dorsum of the penis compresses it downward. This causes a pretty firm closure. The patient always willingly assists, as there is a dim tradition extant which undeservedly fell into oblivion of late, that compression of the deep urethra during injection prevents gonorrhea from spreading backwards. The cleansing done, injections of protargol in one-fourth per cent. strength are resorted to; two syringefuls every two hours during the day and twice during the night and each retained from five to ten minutes, yields excellent results. This is the condition in which early heroic treatment secures results almost bordering on abortion of the disease. By some this is claimed to be an abortive cure, and is so utilized in their statistics.

As conditions exist, however, patients will come for treatment when the acme of the florid stage is reached, and purulent, thick, whitish-green pus appears with increased inflammatory symptoms. This usually happens in the second week, and in patients with first infection. If in the judgment of the physician the inflammatory symptoms are not of a peracute character, then an immediate injection, two syringefuls, each retained for five minutes, every three hours, will act with great precision. A somewhat increased discharge will be observed during the first few days, showing al-

most nothing but abundant gonococci-bearing pus cells, epithelium being present only in a scanty quantity. In this form with sufficient leucocytosis and with moderately acute inflammation, interference is justified. In a few days, mostly at the end of the second or middle of the third week, the scene changes; the symptoms indicating a retrogressive inflammation are noticeable, the discharge becomes thinner and mucopurulent and then serous, diminishing in amount, the clinical symptoms gradually becoming milder, resembling the initial stage. Microscopically we will find at this time a diminution of the number of gonococci-bearing pus cells. Transition epithelium with gonococci covering it in clumps appears more frequently in the proportion as the process assumes a subacute aspect or tends toward recovery. As soon as these signs appear we must attend to the secondary lesions caused by the gonococci. These are erosions and fissures. It is in this stage that an astringent is absolutely necessary. Finger recommends in this stage either argentamine or nitrate of silver, but I think that they yet prove to be too irritating.

Subacute Gonorrhea.—This is a gonococcus infection of a milder character. As mentioned elsewhere this form is due either to an attenuated virulency of the gonococcus or to a lessening receptivity of the urethral mucosa. Both factors—the invading and repelling power—being of equal strength a deeper penetration of the gonococcus will not take place. What the process lacks in deep diffusion, however, is equalized by its extension to the adjacent parts. The symptoms being of a milder character they are easily overlooked by the patient and a surface extension may eventually take place by involvement of the posterior urethra and prostate. We consider here only that form of subacute gonorrhea which starts *ab origine* as such, with slow intensity and lenient in form, mostly in individuals that have had one or several attacks, or in those debilitated by some constitutional disorder. I am somewhat suspicious of this form when occurring as a first infection in a robust and healthy individual. Its insidious course invites negligency of attendance from the patient, and probably a somewhat undecided treatment on the part of the physician. I have frequently seen the bulbous part become affected and chronic posterior gonorrhea to develop. If in these cases the discharge contains the above described negative microscopical evidences I recommend active treatment to be initiated at once. If the gonococci-bearing leucocytes are present in a desirable quantity then the treatment should be less active. A medium degree of drug irritation in a sluggish case is apt to bear better results than a vacillating treatment. I do not mean that a mild process must necessarily be turned into a grave one. It is necessary only to give a slight impetus to the deviated natural process, like, for example, the application of the silver nitrate stick to sluggish granulations.

The treatment of this subacute form where the gonococci are located superficially should be pursued with the idea of removing them mechanically as well as remedially. That mechanical antisepsis with chemical agents proves of more value than indifferent solutions was emphasized by Kiss,[89] and also by Joos[90] and Woodruff,[91] who have used hot water, boric acid solutions and decinormal salt solutions with good effect. I regard them only as adjuncts to the antiseptic injections. A one-quarter per cent. protargol solution, one syringeful three times a day, will suffice to cause sufficiently active discharge by increased leucocytosis. While some may look upon this procedure as a somewhat unusual step I regard it necessary for the future welfare of the patient. Want of active inflammation causes persistency of the gonococcus. This is also evidenced by the stoppage of the discharge when epididymitis or inguinal adenitis complicates gonorrhea. It seems that the active inflammation in these parts causes a relative anemia in the urethra with diminished or even arrested emigration of leucocytes and undisturbed persistence of the gonococci in the subepithelial tissues. While I do not coincide with Schlossberg[92] that these complications are a cure—hastening corrective, yet it seems to me to strengthen my contention on the eliminative value of active congestion. Quite recently I have occasion to extirpate a packet of deep inguinal glands complicating a subacute form of gonorrhea. During the time that efforts were made to cause absorption by conservative means the discharge dwindled down to a small mucous drop with hardly any gonococci, appearing only on stripping the urethra. Twenty-four hours after operation a free discharge laden with gonococci reappeared, and the active urethritis was treated and cured without further complications.

The further treatment of all these forms of acute gonorrhea conform to the *microscopical* evidences. As soon as the leucocytes do not predominate any more and a liberal admixture of columnar or pavement epithelium supervenes with gonococci upon them and also free, we have arrived at the stage of decrease or terminal subacute stage. I then resort to astringents, using a one-half per cent. solution of zinc sulphate, alternating with the antiseptic four times a day, each being used every four hours. In the proportion as the gonococci and pus corpuscles diminish and give room to transition and pavement epithelium cells in the discharge the antiseptic injection is used in the morning and at bedtime, while the astringent is injected twice during the day. Soon the discharge will be reduced to a scanty morning drop, and then we have to turn our attention to the character of the shreds. So long as they contain gonococci and pus cells the alternate use of antiseptic and astringent injections must be continued. It will happen sometimes that gonococci are not present in the shreds while pus corpuscles are abundant. This calls for the alternate treatment yet, as the presence of leucocytes is always indicative of gonococci and secondary lesions. But if gonococci are absent and pus cells present

only in small numbers, diligent microscopical examination showing their gradual disappearance, while abundant epithelium indicates the final process of desquamation, then irrigation with the large hand syringe of silver nitrate solution of from 1 to 4,000 up to 2,000, without catheter, every other day, will prove highly curative to the secondary lesions. If the discharge shows up again I have found permanganate of potash in this stage, 1:6,000 to 4,000 extremely useful in allaying the effects of a previous overstimulating treatment. It may happen that through indiscretion or otherwise a subacute exacerbation may cause gonococci to reappear. Washings of the anterior urethra with a mild protargol solution (one-quarter per cent.), using the large syringe, will then be in order, while the patient uses an astringent at home. If the exacerbation yields a discharge containing streptococci and staphylococci and other bacterial contamination besides mucus, fibrin, and epithelia, characterizing the so-called secondary infection or bacillary nongonorrhoic uretritis, mentioned elsewhere in this paper, then flushing with bichloride solution 1: 20,000 to 10,000, must be employed. A viscid grayish scanty discharge in the meatus, which under the microscope shows only mucus and epithelium embedded in a network of fibrin, an occasional pus corpuscle and chains of cocci, is either a simple postgonorrhoic terminal catarrh or due to overtreatment. Gradual cessation of treatment and rest will soon cause its disappearance.

Cure.—This ends the injection treatment. The patient is now directed to report once a week. The usual mode of life is resumed gradually. If no discharge shows up within two weeks he is permitted to partake of alcoholics. The beer tests or a provocative injections of nitrate of silver, 1:1,000, are now tried either singly or together. Discharge following should be examined not earlier than twenty-four hours after its appearance, the urine to be centrifugated and the deposit examined. If after repeated examinations there are no gonococci present the patient may be regarded as cured. But I am in the habit of examining the patient once a month for three months. If no discharge is obtainable and if the shreds are negative I obtain some secretion for microscopical examination by expressing the prostate and seminal vesicles. In uncomplicated cases the Thompson two-glass test will prove sufficient. If posterior involvement is present the Jadassohn-Goldenberg three-glass test or Kollmann's five-glass test should be employed. These steps, however, serve to determine the seat of chronic gonorrhea, which is not within the province of this paper. I have dwelt on these points elsewhere.[93]

The complications of gonorrhea demand immediate cessation of active treatment. Edema, lymphangitis, chordee, ardor urinæ, cavernitis have been dwelt on under peracute gonorrhea. When acute posterior gonorrhoic urethritis, or urethrocystitis, or involvement of the prostate and epididymitis, etc., appear as much dreaded complications I adhere to the same principles that govern me in the treatment of the different enunciations of acute anterior urethritis. In the face of promodern theoretical reasoning to pursue active treatment, I feel satisfied that by employing rest, antiphlogistic and symptomatic treatment until the storm is over, I have done more for the comfort and safety of the sufferer than by pursuing to the bitter end the results of laboratory investigations. The stranguric patient's urethra is not a simple culture medium, in which the gonococci must be killed at all hazards. This test tube has sensitive nerves. The peracute symptoms over, active treatment can be gradually resorted to.

It is very difficult to enumerate all possible enunciations of acute anterior gonorrheal urethritis. In the foregoing some of the more common ones were merely alluded to. It is a sound principle to conform our treatment to the condition of the mucosa borne out by the microscopical evidences. The microscope is an absolute necessity for the intelligent treatment of gonorrhea. The methods of staining specimens—a useful, interesting and a not too difficult exercise—should be mastered by every practitioner treating gonorrhea. He will be amply rewarded by the results. That gonorrhea is a serious affection, especially in its later manifestations, must be impressed upon the patient as well as upon those of our ranks, who yet look upon it complacently as "only a little clap."

The treatment and handling of the affected parts should be done in a clean and aseptic manner. Both physicians and patient should beware of infecting their eyes. Ablution of the parts with a 4 per cent. boric acid solution should precede treatment. The hand syringe used by the patient should be kept in a clean piece of sterilized gauze. Before using it should be squirted through with hot water.

Realizing that there is still a considerable difference of opinion in reference to the treatment of gonorrheal urethritis, it occurred to me that it might prove both interesting and instructive to institute an inquiry which might afford some positive deductions in this vast field of negations. A list of questions was sent to 240 genito-urinary surgeons throughout the United States, of whom 127 responded, and I take this opportunity to extend to them my cordial thanks. Of these 29 failed to give any definite information for various reasons, and their answers cannot therefore be utilized. As my correspondents include many of the leading genito-urinary specialists in this country the results of this inquiry may be regarded as an authoritative expression of the present views on the treatment of gonorrheal urethritis.

To the question, "Is the destruction of the gonococcus the chief aim of your treatment?" 75 per cent. responded in the affirmative.

In reference to the inquiry, "Have you found the abortive treatment of value?" the views expressed are about equally divided, and this was also the case with the question, "Is it your cus-

tom to begin with local treatment in the most acute stage of the disease when highly inflammatory symptoms are present?"

The inquiry, "Which mode of treatment do you prefer, irrespective of the drug used: (the Janet method of hydrostatic irrigation; flushing with the large piston syringe, or injection with the full-sized hand syringe?) elicited no definite answers, since some correspondents had no choice.

In answer to the question, "Which among the new silver preparations has given the best results in your practice?" 50 per cent. expressed a preference for protargol, 50 per cent. preferred other silver salts (argonin, argyrol, argentamine, albargin, and sublamine).

It seemed interesting to determine whether complications are less frequent when the new silver salts are used, and in response to my inquiry on this point nearly 75 per cent. expressed themselves in the affirmative.

The inquiry, "What percentage of gonorrheas so treated by you becomes chronic?" gave rise to a wide difference of opinion. While about 20 per cent. of my correspondents stated that under their special treatment the disease rarely, if ever, assumed a chronic type; about 30 per cent. were doubtful, and the remaining answers ranged from 1 to 50 per cent. of cases.

Although I am aware that from such a limited number of data covering different conditions and drugs no definite conclusions can be deduced, yet it gives a partial outline of the prevailing ideas on this mooted question.

The majority of the correspondents seem to be imbued with the idea of the extreme chronicity of gonorrhea. The same majority are convinced also that some treatment should be instituted. It is this vast proportion of medical men that advocate mostly treatment on conservative lines. It is surprising that the abortive treatment, according to the returns, has such a large number of adherents. This, in my opinion, is due to the use of the new silver salts, as their lack of irritation in comparison with nitrate of silver makes their employment less painful and risky. As a large number commence treatment when highly inflammatory symptoms are present, this would seem also due to the new silver salts and their mildness of action. There is a wide difference of opinion. They have narrowed down considerably, the choice of the remedies answering the definite indications based on the biology of the gonococcus.

THE DIAGNOSIS OF INCIPIENT PULMONARY TUBERCULOSIS.

BY GEORGE WILLIAM NORRIS, A.B., M.D.,
OF PHILADELPHIA.

PHYSICIAN TO THE MEDICAL DISPENSARY OF THE EPISCOPAL HOSPITAL, AND OF THE HENRY PHIPPS INSTITUTE; EXAMINER TO THE WHITE HAVEN SANITARIUM.

So much has already been aptly said and well written upon the diagnosis of incipient pulmonary tuberculosis, that I can hardly hope to bring forward any new or original thoughts on the subject. I shall try, however, to emphasize some facts which have been indubitably proven, but which are at present inadequately recognized.

Unfortunately the onset of tuberculosis is accompanied by such slight symptoms, that when the patient presents himself for treatment, several months have usually elapsed since the implantation of the tubercle bacillus first occurred; but a recognition of the disease even at this time is as a rule sufficiently early to justify the expectation of a cure.

The most common symptoms of pulmonary tuberculosis are, loss of bodily weight and strength, with failure of appetite and a tendency to become easily fatigued,—a symptom-complex which is generally summed up by the expression "run down." It is a safe axiom to assume that every hemoptysis is tuberculosis in origin until proved otherwise; and a similar rule may be laid down for an attack of bronchitis, which, without evident cause, lasts for more than six or seven weeks. A mode of onset which is fairly common, but by no means generally recognized, is that of pain and stiffness of the joints. In these cases the lungs are often not examined, and the patient is treated with various antirheumatic remedies without benefit. Observation is teaching us that quite frequently chronic arthritis is of tuberculous origin; and certainly arthralgic pains and peripheral neuritis are very common in tuberculosis of the lungs, as are also slight pain in the shoulders and back, and vague sense of oppression or discomfort in the thorax.

Distinct pain in the chest, due to a pleuritis, is usually not an especially early manifestation; neither are chills, fever or night sweats, at least not when these reach sufficient proportions to be complained of by the patient. Slight fever, however, of which the patient is unconscious, especially if recurring regularly towards evening or after exertion, is very suggestive. This pyrexia is, as a rule, very slight in amount, being perhaps only one-half or one degree above the normal, on which account it is often disregarded. Night sweats, too, are often trivial; they may be confined to the axillæ, and be attributed to an abundance of bed-clothes. Vasomotor paresis and cardiac erythism are frequently encountered; the former manifesting itself by transient erythema and sudation; the latter by tachycardia, which is still more increased by slight exertion or mental excitement; this acceleration of the pulse accompanied by dyspnea on exertion is very characteristic.

Prolonged or frequent hoarseness should always be carefully investigated, as should also dyspepsia, prolonged diarrhea or other gastro-intestinal symptoms. Cessation of the menses in women does not usually occur until the disease is considerably advanced. It should always be borne in mind that pulmonary tuberculosis—especially when the infection is a simple one—may not only exist, but even be well advanced, without the patient having been conscious of cough. All attacks of pleurisy should be treated as "suspects." A large proportion of these cases subsequently develop tuberculosis of the lungs, and have a similar origin. If effusion is present the aspirated fluid may be shown to contain tubercle bacilli, this being most accurately demonstrable by animal inoculation.

Careful questioning in regard to the patient's personal and family history will often beget information of the most useful character. In about two-thirds of the cases the source of infection can thus be learned and valuable data obtained as to the amount of time which has elapsed since the primary implantation took place; from which deductions may be drawn regarding the course which the disease has and probably will run. A second attack of supposed typhoid fever, or an unusually protracted siege of influenza, will often indicate the time when the tubercle bacillus first became pathologically virulent.

Attention has often been called to the habitus phthisicus—a flattened, elongated chest, with prominent clavicles and scapulæ, glistening bluish-white scleræ, dry, fine, brittle, lusterless hair; sunken or hectic cheeks; sharp nose; mydriasis; a red line on the gums, and other well-known signs. Any or all of these may be present, although usually not in early cases, and may be of help in making a diagnosis, but their absence should never throw us off our guard. Distinct tubercular lesions are often found in apparently well-nourished and robust individuals. The presence of slight spinal curvature, or of scars on the neck, the result of a lymphadenitis in early life, are much more important findings. Physiological sufficiency of the thorax is more to be looked for than mere anatomical configuration.

Physical Signs—At the very outset I should like to emphasize the necessity, in every case, of an entire and absolute exposure of the chest when making a physical examination. It is often stated that the majority of heart lesions may be correctly diagnosticated by inspection and palpation; but in no phase of internal diagnosis can more be learned from inspection alone than in pulmonary tuberculosis. Two reasons why this disease is so frequently overlooked is, that the lungs are examined through the clothing, and that the stethoscope is not employed. The latter is no less essential than the former, not only for careful localization, but in order to auscult certain regions at all; notably the supraclavicular fossæ, and the axillary apices, two of the most important regions.

Inspection of the chest should be made under good illumination, and care should be taken to

have the shoulders lowered and the muscles of the shoulder girdle relaxed. By standing alternately a little distance in front of the patient, and again by looking over the shoulders from behind, changes in the respiratory movements can be readily detected. On the affected side diminished or delayed expansion will be found, perhaps also restricted diaphragmatic excursion, the latter being due either to pain or to adhesions of the pleura. Supraclavicular and infraclavicular depression, or subclavicular flattening will often indicate the location of the lesion. Inequality of thoracic expansion can be very readily determined by means of a tape measure in which the ascending scale of inches is laid off in each direction from the middle. Distinctly restricted movement on one side of the chest without evident skeletal deformity should make us very strongly suspect tuberculosis.

Palpation is perhaps the least valuable of the four routine methods of investigation; doubtless because a thickened pleura vitiates the physical signs as evinced by fremitus. As a rule, however, corroborating evidence to that obtained by inspection will be produced, especially in regard to the amount and relative extent of the expansion.

Percussion usually elicits a change of resonance, which may range from slight impairment to absolute flatness; the note depending largely on the character, extent and depth of the pulmonary involvement, as well as upon the amount of pleural thickening or compensatory emphysema present. The apices of the lungs above the clavicles being near the surface should always be lightly percussed. Deep-seated lung involvement requires forcible percussion to elicit changes in resonance. The use of the fingers alone in percussing is to be preferred to artificial pleximeters, owing to the very valuable sense of resistance which is thus retained; at times, however, slight changes in pitch can be more easily detected by the use of an ivory instrument.

A careful comparison of corresponding areas should always be made, bearing in mind that under normal conditions the resonance is usually more marked in the right chest. If percussing the anterior surface, the patient's arm should hang relaxed at the sides; if posteriorly, the hands should be placed on the opposite deltoids; if in the axillary line, they should rest upon the head, the elbows being thrown slightly backward. As far as possible muscular relaxation should be attained, and the patient's head be held in the same planes as the body.

Percussion over a tuberculous area frequently produces pain, especially if there is marked pleural involvement; when performed over a cavity it is often productive of cough and expectoration; the latter phenomenon when occurring is, I think, very suggestive of a vomica. If the lesion is deep-seated and compensatory emphysema exists, hyperresonance may replace impairment. Abrams especially insists that tympany and not dulness is the note most often encountered in early tuberculosis.

In the acute differentiation of the percussion resonance the personal equation enters largely into account. An ear which readily analyzes musical notes will always be more expert in pulmonary diagnosis, other things being equal; but in every case special education and practice are necessary. It is not enough to be able to distinguish changes in sound; we must also be able to recognize the amount of their deviation from the normal, and to interpret their pathological import, if such they have. It is a safe plan to begin percussing over a part of the lung which we know to be healthy, and gradually approach the part which we know to be diseased. In this way we refresh the memory as to what true resonance is, or at least measure the extent to which it exists in the individual in question.

Auscultation reveals the most important information. Before resorting to it, however, it is well to spend some time in instructing the patient to breathe properly, "a little deeper than naturally," and seeing to it that he does so, before listening to the chest. This procedure is very time-saving in the end and eliminates many possible sources of error. If the patient's neck is craned forward or backward, and in some cases even in a straight position, rancous, throaty sounds will be transmitted to the chest, which may closely simulate bronchial breathing, and be the cause of much confusion. Stenosis of the trachea or pressure upon the bronchi from aneurism, tumor or enlarged bronchial glands, may produce a similar result. These cases are differentiable from tuberculosis through the equal bilateral quality of the sounds produced, and by the absence changes in resonance. Expiration should be passive, no voluntary expiratory effort being made. Patients suffering from any nasal obstruction should breathe through the oral cavity.

The entire chest must, of course, be carefully ausculted, but special attention should be paid to the apices above and below the clavicle, anteriorly; the supraspinous fossæ and the areas which underlie the inferior extremities of the scapulæ, posteriorly. The latter areas correspond to the fissure between the upper and lower lobes. If râles are absent, the patient should be made to cough forcibly and take deeper inspirations; a procedure which will often cause doubtful findings to become clear pathological manifestations. In the early stages of pulmonary tuberculosis glaring physical signs must not be expected. Expiration may be but slightly prolonged, or perhaps only roughened; in some instances an unduly suppressed and indistinct respiratory murmur is equally indicative of disease. Bronchial breathing does not occur until marked infiltration has taken place. Fine, hair-like crepitant râles, heard especially at the end of inspiration, localized to a certain area, though not necessarily the apex, are very characteristic of tuberculosis; but often much coarser râles may take their place or be commingled with them.

There is much truth in the hackneyed adage that a "unilateral catarrh is not a catarrh." Due,

but not too much, allowance must always be made for the bronchovesicular respiration which is normally encountered, especially in women, posteriorly over the bronchi; and anteriorly at the second right costosternal articulation. Tuberculous foci in the latter location have to be determined by the percussion changes, the pressure of râles, the date obtained by inspection, etc. The normal breath sounds at the right apex, similarly to the resonance, are more intense than on the opposite side. Pleural friction sounds are not infrequently heard over infected areas, coincidently with râles; they are usually low in pitch, rough, grating in character, unchanged by coughing, intensified by deep breathing, and remain localized for extended periods of time. Such frictions may be simulated by the sounds which the scapulæ sometimes produce in rubbing over the dorsal fascia; the latter, however, can be made to disappear by changing the position of the shoulder-blades.

As has been already stated, great care should be exercised to secure complete relaxation of the thoracic and dorsal muscles, because the sounds produced by contracting muscle fibers may considerably modify the character of the respiratory murmur, and a patient who is straining or even exerting his voluntary muscles will not breathe in a soft, natural and effortless manner.

But little attention should be paid to cog-wheel respiration. This phenomenon may occur from irregular contraction of the respiratory muscles, and is very common in excited or neurotic patients. It is noted in many non-tuberculous cases, especially anteriorly near the heart, and in lung areas overlying the large vessels. Subclavian murmurs are frequently observed; they usually appear or become intensified toward the end of a deep inspiration, and are apparently due to constriction of the vessels by consolidated lung tissue or adhesions. When heard they are perhaps suggestive, but by no means pathognomonic, of tuberculosis. Accentuation of the pulmonary second sound is a very constant finding, even in early cases. Cardiac murmurs are by no means rare; they may be due to anemia, relative insufficiency of the valves or otherwise abnormal heart action. Distinct organic valvular lesion, while by no means excluding tuberculosis, as formerly supposed, are not very frequent complications. Cardiac-respiratory murmurs are often met with; they possess neither diagnostic nor clinical significance.

The detection of tubercle bacilli in the sputum is satisfactory evidence as to the etiology of the condition; their absence, however, is no disproof of it. The sputum of advanced cases, with well-marked evidences of cavity-formation, often has to be examined a number of times before tubercle bacilli can be demonstrated; and in incipient cases often 20 or 30 examinations are required before a positive result can be obtained. Truly incipient cases have, as a rule, no expectoration whatsoever, the cough itself being often unnoticed by the patient. The present tendency to defer the diagnosis of tuberculosis until bacilli have been found in the expectoration is most unfortunate for the patient, and often humiliating to the physician. No hesitancy exists in telling a patient suffering from cardiac or renal lesions of their true condition, and insisting upon hygienic reformation; but the tuberculous individual, who harbors a far more curable disease than either of these, is allowed to remain in a benighted state regarding his malady until a physical breakdown brings to his own realization the fact that he is afflicted with more than a transient disease. The symptoms, clinical history and physical signs are in many cases sufficient to justify a diagnosis of pulmonary tuberculosis without an examination of the sputum at all; and until this fact is more generally recognized, the future, like the past, will witness the transport of a remediable incipiency to a hopeless advancement before the diagnosis is pronounced.

The demonstration of tubercle bacilli in the sputum may be considerably abetted by centrifugalization, or by the more recently introduced method of inoscopy—which consists of liquefaction of the sputum by a process of digestion before centrifugalization. Animal inoculation when feasible is also of assistance, but requires time and especial facilities. In the light of modern belief the infrequency of tubercle bacilli in early cases is easily explained. Nearly all investigation is tending to prove that this micro-organism is never inhaled directly into the air vesicles, and that pulmonary infection when present has always been preceded by an infection of the bronchial lymphatic glands; the portal of entry having been the bronchial or intestinal mucous membrane, the tonsils, etc. This being the case, the bacilli have literally to come through the lungs before they appear in the expectoration, a process which does not occur until necrosis of the pulmonary tissue has taken place. Large numbers of bacilli, unless continuously found, are not necessarily an indication that the disease is far advanced. They may be due to the breaking down of a small nodule, which happened to occur at the time when the sputum was collected for examination.

The tuberculin reaction is a useful adjuvant in diagnosis, to be held in reserve. While not infallible as a positive test, its absence precludes the presence of tuberculosis. The value of serum diagnosis is still sub judice. The X-ray, laryngeal mirror, and occasionally the ophthalmoscope, have been of distinct value in diagnosis, but unfortunately expert testimony is required to make the evidence thus obtained of material weight.

Differential Diagnosis.—The conditions which most closely simulate incipient pulmonary tuberculosis are syphilis, influenza, and mitral disease, especially slight grades of stenosis, healed tuberculous lesions and simple streptococcic infections of the lung, and non-tuberculous fibrosis. Much diversity of opinion exists as to the frequency with which syphilis affects the pulmonary tissue, but prevalent belief is to the effect that this is more commonly the case than is generally sup-

posed. Aside from a history of such infection, localized evidences, such as cutaneous scars or other tertiary lesions may be present. Syphilis usually begins at the hilum of the lung. It may spread upward, but more usually affects the lower lobes. Tuberculosis begins just below the apex, and generally affects the adjacent lobe before spreading to the opposite side. In syphilis there is, as a rule, equal bilateral consolidation, often without râles; emaciation, expectoration and fever are less marked, hemoptysis is more rare. The patient seems much less ill than would be the case from an equal amount of tuberculous pulmonary involvement. The tuberculin test is of no value in these cases because syphilitic patients sometimes give a positive reaction. A laryngeal examination may be decisive if this organ is involved; but generally the diagnosis hinges upon the sputum examination and the therapeutic test—tuberculous patients being nearly always made worse by the administration of mercurials and iodide of potassium.

Influenza and pulmonary tuberculosis are more frequently confused; but here the protracted course of the latter, the presence of a slight regular evening rise of temperature, night sweats, hemoptysis, progressive emaciation, accentuation of the pulmonary second sound, localization of the physical signs and tubercle bacilli in the sputum are features of differentiation. As has already been stated, many cases of supposed influenza are acute exacerbations of pulmonary tuberculosis. The mere recurrence of such attacks, especially if subsequently the health of the individual remains impaired, should make us very suspicious of tuberculosis. If a diffuse bronchitis co-exists it is often necessary to defer a positive diagnosis until the latter has cleared up.

Slight traces of mitral stenosis may render the diagnosis for a considerable time uncertain. In either condition we may have a rapid pulse, cough, expectoration, râles, easily provoked dyspnea and fatigue, gastric symptoms, accentuation of the pulmonary second sound, hemoptysis, etc. But here again cyanosis, with marked right-sided cardiac enlargement, diffuse unilateral involvement of the lungs, most marked at the bases, without pyrexia, as well as the absence of night sweats, are evidence in favor of a heart lesion. The blood pressure in mitral stenosis is apt to be slightly above the normal, while in tuberculosis arterial hypotension frequently exists. Precordial thrills are commonly encountered in the last-named disease, owing to general emaciation or to retraction of the lung; but when unaccompanied by mitral stenosis they are not presystolic in time.

Healed tuberculous lesions, if complicated by an acute infection such as bronchitis, require more or less prolonged observation, frequent examinations, and careful consideration of the anamnesis, subjective symptoms and general health.

Non-tuberculous fibrosis is to be recognized by its equal bilateral character, absence of fever, hemoptysis, tachycardia, night sweats, etc., but especially by the disproportion between the amount of lung tissue involved and the apparent illness of the patient, as well as by the absence of tubercle bacilli.

Some of the most puzzling cases are those which occur in old people, in whom the respiratory sounds are suppressed, or in those who are known to have emphysema, with perhaps cardiac and renal degeneration as well; in which the question arises as to the additional presence of an active or a healed tuberculous lesion. Such cases necessitate repeated physical examinations and the employment of all available diagnostic means. Fortunately, the diagnosis in these instances is of less moment than when occurring in patients of an earlier age; inasmuch as the tuberculous process is apt to run a slow and protracted course, so that under reasonable hygienic conditions the length of life is not naturally shortened thereby.

Simple localized lobular streptococcus infections of the lung, such as have been described by Finkler and A. Wassermann,[1] may so closely simulate tuberculosis as to be differentiable only by the continued absence of the tubercle bacillus from the sputum and a negative tuberculin reaction. Such cases, compared to the prevalency of tuberculosis, do not occur with sufficient frequency to make their similarity of much clinical importance.

It is always well to defer a positive diagnosis in cases of complicated pleural effusion, bronchitis or any other acute infection. A certain number of cases are encountered which for a time baffle even the most expert diagnostician. But repeated and careful examinations will usually solve the perplexity. The diagnosis of incipient primary tuberculosis should be within the power of every physician. The vast majority of cases require neither special facilities nor unusual abilities for their detection. It is largely a question of care and common sense, together with a reasonable degree of efficiency in medical knowledge and physical diagnosis.

It is a deplorable fact that many practitioners to-day are either unable or unwilling to diagnosticate pulmonary tuberculosis in its early stages. This is in part due to the general skepticism which exists to a greater or less extent in regard to the curability of the disease. To some members of the profession the fact that the patient makes a satisfactory recovery at home in the course of a few months is a proof that the disease was not pulmonary tuberculosis; notwithstanding the fact that nearly every human being has harbored some tubercle bacilli in his system at some stage of his career, and that autopsy statistics reveal distinct tuberculous lesions in nearly one-half of all cases dying from other diseases. The frequency with which supposedly incipient cases of tuberculosis are sent to the examiners of the White Haven Sanatorium, who upon examination are found to have two, three, or even more lobes of the lung distinctly involved, is almost beyond belief. Non-

[1] Fränkel Spezielle Pathologie und Therapie der Lungenkrankheiten, 1904.

tuberculous cases are not often diagnosticated as tuberculosis; but the reverse, unfortunately for the patient, is a common occurrence. It is time for the medical profession at large to realize more fully that attacks of chronic bronchitis, bronchopneumonia, influenza, typhoid fever, etc., less frequently "go into consumption" than that they are manifestations of tuberculosis from the onset. "It is probable that if the physician resisted his life-long habit of optimism and erred in the opposite direction in cases of suspected tuberculosis, the mortality list would be shorn of a measurable proportion of its bulk."—(Butler.)

The crusade against tuberculosis, which is having an awakening in this country, cannot be efficiently carried out by a few specialists alone. Neither will the multiplication of sanatoria throughout the land be of benefit to the population as a whole, or bear such fruits as will justify their erection, until the medical profession at large is able to recognize pulmonary tuberculosis in its incipiency, and is willing to send patients to these sanatoria who are still in a curable stage.

DIAGNOSIS OF ADVANCED TUBERCULOSIS.

BY FRANK A. CRAIG, M.D.,

OF PHILADELPHIA.

In taking up a subject which presents so many varied forms it becomes necessary to group the different types together in some systematic way in order to bring it within the limits of the present paper. The classifications according to distinct clinical types or depending on distinct pathologic conditions are too elaborate, except for a detailed study, the cases running one into another so closely and changing so constantly. The classification of Turban has been selected for the reason that, although somewhat crude and restricted, it possesses the advantage of simplicity, and further takes into account not only the local conditions, but also the constitutional effects of the disease.

Turban divides the cases into three classes: *Class I.* Mild cases, infiltration of at most one lobe, or two half lobes. *Class II.* Mild cases, infiltration of at most two lobes; or severe cases, infiltration of at most one lobe. *Class III.* All cases not included in Classes I and II. This paper will only consider Classes II and III, considering them together.

The diagnosis of tuberculosis has passed through various phases or epochs, determined by different important discoveries which had marked influence upon the methods of that period. Perhaps the first great step in more recent times was brought about by the work of Laennec, which started the era of diagnosis by "physical signs," at which time the diagnosis was based entirely upon the examination of the patient, with a tendency to disregard the history of the case and the symptoms. Later, under the stimulation of Koch's great discovery, it suddenly passed into the era of "bacteriologic diagnosis," at which time the enthusiastic supporters of this method disregarded physical signs and depended entirely upon the finding of tubercle bacilli in the sputum for their diagnosis. The influence of this idea has not been entirely overcome in the present day. With improvement in the method of treatment, which emphasized the importance of early diagnosis, every effort was bent upon discovering some absolute means of early diagnosis other than those in use. Thus the era of "early diagnosis" is characterized by various methods of diagnosis, each with its group of adherents all more or less enthusiastic. Even the most devoted followers of the Roentgen rays, tuberculin reaction, examination of the cellular elements of the blood, blood-serum agglutination tests, study of the temperature after exercise, and chemical examination of the urine as a means of diagnosis, emphasize the importance of merely considering them in conjunction with a thorough study of the case itself.

The age, sex, habits, social condition and general history have, of course, the same bearing in an advanced as in an early case, and I will only mention one or two points which have special significance in the former. The exact, or as nearly exact as possible, determination of the duration of the disease is important in its relation to the amount of involvement, when considering the nature of the condition present. This is true also of the general surroundings and mode of life of the patient. For example, a patient who has only slight involvement of long duration under unfavorable circumstances is distinctly different from a patient with extensive involvement of short duration under favorable circumstances. This point belongs perhaps more to a consideration of the prognosis and treatment, but a diagnosis is of little practical value unless it includes not only the presence of, but also the character of, the involvement.

In describing the symptoms I have tried to give, wherever possible, the proportion of cases of tuberculosis in which the different phenomena occur. The figures are taken from the statistical reports of Roepke and Turban, for the reason that these two authors use the same classification, to which I have already referred.

The symptoms to be considered are cough, loss of weight, hemorrhage, night sweats, chest-pains, dyspnea and cardiac palpitation.

Cough.—This is perhaps the most frequent symptom in advanced cases of tuberculosis, it being extremely rare for cases to proceed to this stage without more or less marked cough. That cases may rarely go on to even cavity formation without severe cough should never be lost sight of. It is in no way characteristic, varying in time, character and degree. The expectoration also varies greatly, both in quantity and appearance, from the thick, tenacious, nummular sputum to fetid purulent material. The morning cough with expectoration, due to the retention of secretion over night, may first attract the patient's attention to the presence of cough, but is not distinctive. Both authors quoted give this symptom as occurring in 100 per cent. of cases in this stage.

Loss of Weight is as common a feature as the foregoing symptom. It varies from merely slight loss, which it may require very careful questioning to bring out, to marked emaciation. It is generally progressive with occasional slight remissions under favorable circumstances. This was also present in 100 per cent. of cases.

Hemorrhage.—When it can be definitely determined that the hemorrhage is from the lung itself, this is a most valuable sign. It may not infrequently be the first symptom to call the patient's or the physician's attention to the lungs. The nature of the hemorrhage in regard to its cessation, whether spontaneous, following violent effort or trauma, is important. The statistics quoted by Osler in regard to hemoptysis in general give interesting figures. Of apparently spontaneous hemoptysis about 86 per cent. are due to tuberculosis, of those following exercise about 74 per cent. are due to the same cause, and of those following trauma 50 per cent. are not due to tuberculosis. On the other hand, 70 per cent. of Roepke's cases had hemoptysis and 61 per cent. of Turban's. Mitral stenosis as a cause of hemoptysis is not uncommon and should always be excluded.

Night Sweats.—Although not quite so frequent as the former symptom, they are not uncommon, occurring in 55 per cent. of Turban's cases. They may occasionally be very severe in character and form a most distressing symptom. They occur most frequently in the early morning hours.

Chest-pains.—These may occur between the shoulder blades, in the shoulders, or in the sides of the chest, the two first mentioned occurring more frequently in the early cases. The pains in the chest itself are much more common in the advanced cases, due either to an extension of the tuberculous process to the pleura or to some associated inflammatory process.

Dyspnea and cardiac palpitation, although in no way distinctive, are not uncommon symptoms. The former frequently may cause the patient great distress, and does not seem to bear any constant relation to the amount of lung tissue involved.

Fever.—This is not a constant feature, but the cases are extremely rare that do not show some elevation of temperature at some time during the twenty-four hours. This elevation may be slight and detected only by careful methods in using the thermometer, and frequently goes undetected when these precautions are neglected. I refer to insisting upon the patient keeping the thermometer well under the tongue, the lips kept tightly shut, not taking the temperature directly after the patient has taken anything hot or cold, and being careful to leave the thermometer in the mouth from six to ten minutes. The type of fever varies greatly, not only in different cases, but in the same patient at different times. An afternoon or evening rise with morning remissions or intermissions is by far the most common. This rise may be very high at times, with marked intermissions, and shows, as a rule, decided irregularities. Some writers lay great stress also upon a premenstrual rise in the temperature in tuberculous female patients, and others upon a rise in temperature following exercise.

Pulse.—A rapid pulse is the rule, not always proportionate to the degree of fever or even the amount of involvement. Cases which show very slight rise in temperature, showing frequently a pulse of 100, 120, or even 130. The character of the pulse is not typical, although a full but soft and compressible pulse is commonly noted.

Physical Examination.—In the examination of the patient we have the most important method of diagnosis. The signs elicited vary greatly in character and require not only careful but repeated examinations to determine their significance.

Inspection.—By this means one notes the general appearance of the patient, character of skin and mucous membranes, amount of subcutaneous fat and general muscular development. More important, however, are the configuration of the chest and expansion of same during respiration, noting the rate, excursion and a comparison of the two sides. There has been so much stress laid upon the long, narrow, phthisinoid chest, with its vertical ribs, narrow costal angle, and projecting scapulæ that I merely mention it in passing. It is met with quite frequently; Roepke shows 26 per cent. Another type of chest is that with a narrow anteroposterior diameter. Any form of chest, however, may be the seat of tuberculosis. Localized retraction or tardy expansion of either one or both apices, especially depression above or below clavicles, are also valuable when present, and when sought for carefully will be found not infrequently.

Palpation is mainly useful in confirming inspection, especially in detecting diminished expansion, and in estimating vocal fremitus, the latter being increased over consolidation or cavity, and diminished over collections of fluid or thickened pleura.

Percussion.—On percussion the note will vary according to the amount of infiltration, consolidation, excavation of, or effusion into, the tissues beneath it. Where the infiltration is disseminated, and there is still a comparatively large amount of air-containing lung-tissue between the tubercles, one may get an impairment of the normal note which is extremely difficult to determine. In percussion of the apices one obtains the most important information, as at this point the involvement is further advanced and the signs, as a rule, are more evident. The percussion of the clavicles, supra and infraclavicular fossæ, therefore, gives one the most decided results; especially is this true if only one lung is affected, and one has the opposite lung for comparison. The difference between the two being best brought out by getting the patient to take a deep breath and then hold it, when the percussion at corresponding points on the two sides may show the impairment or dulness to be quite striking. Occasionally the dulness may be more evident posteriorly than anteriorly, and the percussion of the supraspinous

and intrascapular spaces should never be omitted. The note obtained may vary from a slight impairment to dulness, according to whether one is dealing with a disseminated infiltration or a consolidation. Over deep-seated cavities with consolidation around them one may get a note which varies very little from the normal, or may even be dull. Over superficial cavities, however, the note is hyperresonant or even tympanitic. When cavities are quite superficial one occasionally finds the typical cracked-pot sound. It is of importance in percussing the chest that the muscles should be well relaxed; this is best obtained by having the patient in a comfortable sitting position with the shoulders "dropped."

Auscultation.—The auscultatory phenomena are so numerous that I will merely mention those sounds most closely identified with the varying degree of involvement. With slight infiltration one may get merely a prolongation of the expiratory murmur and feeble breath-sounds, or occasionally harsh respiratory murmur, which may be jerky or "cog-wheel" in type. Râles when present are generally fine and crackling, and may be only noted at end of deep inspiration after a cough. As the amount of infiltration advances the respiratory murmur changes, expiration becomes more prolonged and higher-pitched until consolidation occurs, when it becomes bronchial in character. The râles also become more numerous, as a rule, and are larger and more moist in character. Over cavities of moderate size the breath-sounds are cavernous, or occasionally may be amphoric, and râles are large and bubbling. Vocal resonance is increased over any infiltrated area (except where thickened pleura or pleural effusion intervenes) in direct proportion to the amount of involvement until consolidation is reached, when bronchophony or whispered pectoriloquy may be found. The latter is, of course, best heard over cavities, especially when superficially situated. Pleuritic friction rubs may be frequently noted, and are often very hard to differentiate. Considerable consolidation around a bronchus may simulate a cavity very closely.

As to the value of percussion and auscultation in making a diagnosis, some authors claim greater precision in one, and some place more value on the other. It is a personal matter entirely, which must be settled by each one for himself. A careful application of all the methods of physical diagnosis will, perhaps, give the best results.

Urine.—Although the examination of the urine may give very few data in this condition, it should never be omitted. Glysocuria and albuminuria, while not common, occur not unfrequently, the latter in the later stages, due probably to some degenerative change in the kidney. A positive diazo reaction is a very unfavorable sign in tuberculosis; except as an aid to prognosis the test has little value in this condition. Ehrlich's dimethylamidoazobenzaldehyde reaction in the urine is not typical of tuberculosis, as it occurs in numerous other pathologic conditions. Another condition suggested as being indicative of tuberculosis is phosphaturia alternating with albuminuria.

Sputum.—In the examination of the sputum we have a most valuable and positive aid in the diagnosis, and one fortunately that is very easily carried out. The presence of tubercle bacilli in the stained expectoration is an absolute diagnostic sign of tuberculosis. The contrary, however, does not hold good, and the absence of tubercle bacilli from the sputum does not exclude this condition. A frequently repeated and carefully made examination of the sputum will in many instances reveal their presence. Roepke found the bacilli present in 67 per cent. of cases in Class II, and in 100 per cent. in those of Class III. Turban found them present in 89 per cent. of cases in Class II, and in 98 per cent. of cases in Class III.

Tuberculin.—This agent has been highly recommended by numerous observers, more, however, as a means of confirming the clinical examination than as a means of diagnosis in itself. It is useful mainly in early cases, as the results are not so good in the more advanced cases. Its field of usefulness is somewhat limited, however, as it requires keeping the patient under very careful observation for a week or ten days, although one investigator has used it in dispensary cases with fairly satisfactory results. It has not been used to any great extent, owing to the prevalent idea that it may disseminate a localized tuberculosis.

Blood.—The examination of the corpuscular elements of the blood gives very little assistance. The blood counts and findings are not constant. Especially is this true in the early stages, when it would be of most value. The absence of eosinophiles, however, has an unfavorable, and their increase in number a favorable, prognostic value.

The serum agglutination test of Arloing-Courmont is unreliable, as shown by numerous observers. The technic is also too elaborate for general use, requiring laboratory facilities for its performance.

Roentgen Rays.—Although quite satisfactory results have been obtained by the use of this method, it requires a careful special training in order to be of any value at all.

DIFFERENTIAL DIAGNOSIS BETWEEN PULMONARY TUBERCULOSIS AND CONDITIONS RESEMBLING IT.

BY H. R. M. LANDIS, M.D.,
OF PHILADELPHIA.

The conditions simulating advanced pulmonary tuberculosis are so numerous that lack of time will necessitate only a brief reference to many of them. Therefore, I will restrict this paper to those conditions which have caused errors in diagnosis, both by members of the staff of the Phipps Institute and by members of the profession who have referred cases to the Institute.

Most of us have a definite picture of pulmonary tuberculosis in its advanced form, and a case giving a history of loss of weight, cough, expectora-

tion, hemoptysis, fever and night-sweats in association with certain physical signs is usually looked upon as most certainly tuberculous.

There are two points, however, which, if kept in mind, will obviate many mistakes. The first is that pointed out by Fowler, namely, that there is a definite "line of march" taken by the invading tubercle bacillus. The disease almost always starts just below the extreme apex on one side and pursues a downward course. The lower lobe of the lung first affected is almost invariably involved before the apex of the opposite side is attacked. This always results in the disease being in a more advanced state at the apex than in the lower lobe.

The second point of importance is the examination of the sputum in all cases of pulmonary disease. While too much stress has undoubtedly been laid on the finding of tubercle bacilli in incipient tuberculosis it can be safely said that too great laxity prevails in similar examinations in what are apparently advanced cases. Systematic examination of the sputum is insisted on at the Brompton Hospital, and this precaution alone has led to the detection of many obscure conditions.

In taking up the diseases which simulate tuberculosis it may be said that some of them are quite rare and can be dismissed with a word. Actinomycosis, aspergilesis and hydatid disease depend for their recognition on the absence of tubercle bacilli and the positive identification of the rav fungus, mycelium of hydatid booklet. The same brevity may be applied to intrathoracic growths which are usually evident from the history, pressure symptoms and physical signs.

Among the common conditions causing confusion is *chronic bronchitis.* This is particularly the case in advanced life, where the tuberculosis often runs a latent course, with a normal or subnormal temperature, and the associated emphysema masks the physical signs. The diagnosis in such cases offers considerable difficulty, and may be impossible without the finding of the tubercle bacillus. There is nothing distinctive of tuberculosis either in the symptomatology or the physical signs. Suspicion as to the true condition may be aroused, however, from the following points: The cough, while worse in winter, never entirely disappears; on physical examination it may be noted that the signs are more marked at both apices or at one apex alone; and in addition a definite history of exposure or family predisposition may be present.

Bronchicctasis.—This is a not uncommon source of error, especially in the diffuse form in which the bronchi of a lobe or even an entire lung may be dilated. The dilations may be sacculated, cylindrical or fusiform. The condition is almost invariably secondary to some prolonged inflammation of the bronchi or to induration or consolidation of the surrounding tissue. Therefore a history of prolonged bronchial inflammation, measles, whooping cough, pleurisy, and particularly pneumonia, is important.

There is no single symptom of tuberculosis which may not be present in this condition, but there are several points which render the diagnosis probable, and with the absence of tubercle bacilli it becomes almost a certainty. Cough, expectoration and dyspnea are the important symptoms. The expectoration is quite characteristic, occurring in large quantities at a time, and particularly on rising in the morning. The dyspnea is variable, depending on the extent of lung tissue involved and the implication of the right heart. Pain in the chest is frequent and important, usually indicating extension of the process to the surface of the lung. Fowler states that clubbing of the fingers is so extreme as to be of value in the diagnosis. In three cases I have seen this was certainly true.

The physical signs in the majority of the cases show the lesion to be at the base or about the root of the lung. Fremitus is usually increased, especially if fibrosis coexists. The percussion note depends on the underlying condition: if there be surrounding emphysema the note will be hyperresonant; if the dilations be large the note may be tubular or tympanitic in character; while if fibrosis be present dulness is the result. The breath sounds are bronchial or cavernous, while whispering pectoriloquy and amphoric breathing are present over a superficial dilation. The râles may be large and bubbling and of a metallic character, or, in the presence of fibrosis, superficial and crackling. The "veiled puff" of Skoda may also be present. I have met with this sign in one case. It occurs at the end of inspiration and gives the impression of a puff of air suddenly entering the dilated portion of a superficially placed bronchus.

When the dilations are confined to an upper lobe the differentiation is more difficult. In bronchiectasis of the upper lobes the dulness rarely extends above the clavicle, and the flattening below the clavicle is slight as compared to that in tuberculosis. The greatest source of error is in those cases in which there are signs of a cavity in the interscapular region. While a tuberculous cavity may exist at this point, it is rare without some evidence anteriorly.

Fibroid Lung.—Also referred to as chronic pneumonia, cirrhosis of the lung and interstitial pneumonia.

Pathologically the condition is characterized by an overproduction of fibrous tissue, which tends to diminish the size of the organ and to cause marked retraction of the chest wall. The opposite lung, unless both are involved, shows a marked degree of emphysema. It is believed by some that the pulmonary process is but a part of a general fibrosis, because of the associated arteriosclerosis and contracted kidney sometimes met with. Sir Andrew Clark, Hadley and Chaplin, in their monograph on fibroid disease of the lung, made the following divisions: (1) Pure fibrosis in which there is no tubercle; (2) tuberculofibrosis, a condition primarily tuberculous, but in which extensive fibroid changes have taken place;

and (3) fibrotuberculosis, a condition in which the primary state was fibroid, but subsequent infection with tuberculosis takes place.

Pure fibroid disease is not uncommon in children, and in these cases there is generally a history of some catarrhal affection of the lungs, either measles, whooping-cough or bronchopneumonia. In adults a history of pneumonia is frequent. Other contributing causes are bronchiectasis, inhalations of irritating substances, pleurisy, syphilis and foreign bodies in the bronchi. A long-standing empyema may cause collapse with subsequent fibroid changes. One such case came to autopsy at the Phipps Institute. Two of the authors above quoted believed the condition to be more common in children, while the third had seen more cases among adults. Cough, expectoration and dyspnea on exertion are the symptoms most commonly observed. Marked deformity, as a rule, characterizes the disease. The affected side is retracted; the ribs become approximated, or may even overlap; the spine is drawn toward the affected side, and the heart is pulled out of its normal position, the retraction always being toward the affected side. In right-sided fibrosis the apex beat may be in the fifth interspace in the nipple line on the right side.

The physical signs are variable, and depend largely on the presence or absence of bronchiectasis. When dilations of the bronchi are present the percussion note may be tubular or tympanitic in character; in their absence it is usually dull. With dilation of the bronchi the râles may be bubbling and metallic in character or fine and crackling. The breath sounds may be bronchial or cavernous, or, in the absence of dilations, feeble and distant. The emphysematous condition of the opposite lung gives a hyperresonant note, which may extend beyond the median line of the sternum, and the breathing is puerile in character. Basic heart murmurs are commonly present, usually at the pulmonary orifice, and systolic in time.

In differentiating pure fibroid disease from fibrosis with an associated tuberculosis, the presence or absence of the tubercle bacillus is of course the all-important point. In addition, pure fibrosis runs an afebrile course, the constitutional disturbances are slight, and the opposite lung shows no signs of infiltration or consolidation.

Among the older clinicians, *syphilis of the lung* was looked upon as comparatively frequent. Later the existence of syphilitic disease of the lung was questioned unless it could be demonstrated pathologically. In proof of the rarity of the disease is the experience of Fowler, who states that in a careful search among the museums of the London hospitals he could find but twelve examples of syphilis of the lungs, and in two of these it was doubtful. Recently, however, papers by Janeway, Stengel and Berg would seem to indicate that the condition is not infrequently met with.

Pulmonary syphilis may be strongly suspected if a patient presenting the physical signs and symptoms of tuberculosis has no tubercle bacilli in the sputum after repeated examinations, and in addition has evidences of tertiary syphilis. During the past winter I have seen two colored women who illustrate these points. Both came to the dispensary complaining of cough, profuse expectoration, hemoptysis (in one case), night sweats and loss of weight. The physical signs closely resembled those of advanced phthisis without cavity formation, except that in one case the signs were more marked at the base. In one case there were typical syphilitic leg ulcers, while in the other there were scars on the arms and body of a recent rupial eruption. One case has been lost sight of, but in the remaining case no tubercle bacilli have been found, and she is showing marked improvement under potassium iodide. A case reported by Stengel made a complete recovery under potassium iodide, although he had been admitted to the hospital in a dying condition.

There still remains another condition which experience has shown to be a frequent source of error, namely, *mitral stenosis.* I mention it simply to call attention to the fact that this valvular lesion is a frequent source of blood-spitting. The only cases of mitral stenosis which should offer any difficulty in determining the source of the blood are those in which there is no murmur. In these cases careful examination will usually reveal a faint thrill above the apex beat, accentuation of the second pulmonic sound, a small pulse, and that peculiar quality of the first sound which Da Costa designated as clacking.

In conclusion, I wish to emphasize the importance of keeping in mind the definite "line of march" taken by the invading tuberculous process and the necessity of systematic and repeated sputum examinations in all doubtful cases.

HISTORY-TAKING IN CASES OF PULMONARY TUBERCULOSIS.

BY CHARLES J. HATFIELD, A.M., M.D.,
OF PHILADELPHIA.

In this discussion we are to assume that a patient comes to the examining physician with some indication of tuberculous infection. This indication is to be verified and explained; a diagnosis is to be made and the stage of the disease determined; upon these findings will depend the prognosis and treatment. A careful record of related facts is necessary in the study of any serious illness, and in no disease is the record of greater importance and interest than in tuberculosis, where a history, carefully compiled from the statements of an intelligent patient, is of immense value in helping to determine diagnosis, prognosis, and even treatment.

The records of age, sex, color, social condition, nativity (ancestral and personal) and places of residence are naturally made first. Each of these data has an obvious diagnostic or prognostic value, either in itself or when considered in connection with some significant symptom. Thus a child or a person in middle life will have a more favorable prognosis than will a young adult, or a

patient debilitated by age; a woman will present various forms of tuberculous lesions, *e.g.*, those affecting the uterus and its appendages, which require special investigation; the negro in America is peculiarly susceptible to the disease, and exhibits a power of resistance considerably less than that of the white man; a married patient offers problems in the management of the case quite different from those of the unmarried; a native American is usually much better able to order his life for health and happiness than is a foreign-born immigrant; and the knowledge of the place of residence, whether healthy or the reverse, will aid materially in prescribing for a case.

With the questions as to occupation, family history, habits of life and previous diseases, we enter upon a most interesting field of study, where we may hope to discover the actual exposure to contagion, or at least circumstances predisposing to the disease. It is certainly a gratification to be able to point to some definite association in the history, and to say, with a certainty that satisfies yourself, at least, "There the disease was contracted." The effect of occupation is a most important study. The German authorities pronounce it, when a wage earner is under consideration, of more value than the family history. In this investigation, it is by no means sufficient to know only the present calling of the patient, for a fairly large percentage of cases, having been previously warned that they are "threatened with lung trouble," have in consequence secured positions at outdoor work, as drivers or motormen; whereas, formerly they may have been tailors or cigarmakers. A safe rule is one suggested by a colleague, who is in the habit of making a complete record of all the occupations successively engaged in, and the time spent in each, since the school days. In the list of significant occupations, we can include all those that necessitate a sedentary life, in crowded workrooms, with the possibility of bad ventilation, uncleanliness and dust. In one clinic at the Henry Phipps Institute, during the past year, of 234 cases of tuberculosis, there were 23 tailors, 19 mill hands (operators upon machines), nine cigarmakers, six weavers, six seamstresses, and six clerks—these six occupations supplying almost 30 per cent. of the cases treated.

In the family history, we find most frequently, perhaps, evidence of exposure to contagion. We should have a record of the age and health of each living member of the preceding, immediate and succeeding generations. One is not infrequently able to trace infection to some near relative who has been coughing and expectorating for years, who has a chronic form of the disease that has never been recognized, and who may live long after the victims of his ignorance or carelessness have been buried. The record of family deaths with the ages at death, the fatal illnesses and the dates of death, is still more prolific of interesting facts. In drawing our conclusions, however, we must remember that all tubercle bacilli, even the most virulent forms, lose their vitality in about six months, if we are to accept Cornet's statement, based upon Kitasato's experiments. Therefore, if we are to establish a connection between the condition of our patient and the disease causing the death of a relative, we must be sure that the exposure was either before the death or very soon after. In cases where there is obscurity as to the source of contagion, careful inquiry as to the health of the more remote relatives will often be profitable. When the patient is married, the health of the consort and of the consort's family is of interest and importance. A number of cases can be gathered from the literature of tuberculosis, where a husband or wife suffering from a chronic form of the disease, before succumbing to it, has infected and buried two or more successive consorts.

The question of house infection will naturally be considered in connection with the family history. The fact that tuberculosis is a house disease has been conclusively demonstrated. Therefore, a careful questioning of the patient as to the houses he has occupied during the period of possible infection, together with the character and health of the previous inmates, is often productive of definite results.

The personal habits of a patient have considerable weight in fixing the time and manner of contagion. It is generally admitted that any vicious mode of life, which consumes vital powers and lessens tissue resistence, is predisposing to the disease. Alcoholism, for instance, certainly produces a fertile soil for any infection, and perhaps most frequently for the tubercle bacillus.

When we come to consider the history of previous diseases, we are getting close to the first manifestation of specific activity. When the patient gives a history of a comparatively recent attack of malaria, typhoid fever, pleurisy, pneumonia, or influenza, from the effects of which he has never fully recovered, he may be telling only of the acute illness which left him with a weakened system, an easy prey of tuberculous infection. How frequently, however, we can say, with almost absolute certainty, that the so-called malaria, with its fevers, sweats and slight bronchial irritation, was an acute manifestation of tuberculosis! This error in diagnosis is the one most frequently met with in clinics devoted to tuberculous cases. The same statement is true to a less degree of the history of a recent attack of typhoid fever, where again the fever, prostration, digestive disturbances and the respiratory symptoms have been tuberculous; of pleurisy, which, when primary, is very frequently tuberculous; of pneumonia, with its almost identical clinical picture; and of influenza, that convenient term for any respiratory affection not easily classified. Other diseases which may be of especial interest in the previous history are diabetes, syphilis, gout and rheumatism; and, in childhood, measles, pertussis, scarlatina and diphtheria. The record of traumatism, especially such as would

injure the thorax or cause a long confinement to the bed or room, is often significant.

When we reach this point in our investigation, we are in a position to estimate, with a fair prospect of success, the approximate duration of the disease. If we have a definite source of infection, with a history of symptoms beginning within a few months after the period of contact, the task is easy. We must always remember the extreme chronicity of the disease, and must not hesitate to go back a decade or more in order to find the source whence the sequence of symptoms originated. In this attempt to fix the probable duration of disease, we can hope for no direct assistance from the patient, as his idea of the origin will rarely include more than the beginning of the present acute exacerbation. We must bear in mind, moreover, that the determination of duration is going to affect our prognosis; the fact cannot be disputed that cases who have had tuberculosis for a long time, and who show only moderate involvement, respond to treatment better than do the more rapidly advancing cases. Whether this can be attributed to superior strength of constitution, or to an acquired immunity, it is impossible to say, although the trend of modern investigation seems to point to the latter as the correct view.

In considering the subjective symptoms, we should first record the time when the first sign became manifest to the patient. Usually, a very careful inquiry must here be made, as the patient will easily overlook a gradual loss of weight or strength, or a slight morning cough with expectoration. Next, hemoptysis, whether slight or copious, and when first apparent, must be noted. If pain is present, its location and character are of interest. The character of the cough, whether slight or excessive, worse at night or by day, should be recorded; also the amount, character and color of the sputum. Almost every patient will complain of some dyspnea, slight or marked; and we should make note of how this dyspnea is produced, whether only at night and in paroxysms (asthma) or when lying down (cardiac disease); whether it is continuous, or appears only on exertion. Is hoarseness present? If so, is it persistent or temporary? The presence of chills, night-sweats and edema should also be noted.

The condition of the gastro-intestinal tract should be carefully investigated, for upon its integrity and efficiency, we must largely depend in the modern treatment of tuberculosis. The appetite, the condition of the stomach, whether any dyspepsia or nausea is present, the condition of the bowels, where looseness may possibly indicate intestinal involvement—all these inquiries and records are of vital importance. If the patient is a woman, the periodicity and character of the menstrual flow, or its failure to appear, should be noted. The presence of leucorrhea and its duration is also a matter of interest, because of the theory held by some of our prominent specialists, to the effect that the flow is often indicative of a primary tuberculosis of the uterus or the tubes. Finally, of the subjective facts, we must inquire concerning the previous weight of a patient, recording his best weight and its date, the average weight in health, and the lowest weight since the beginning of the illness. A loss of one-third of the highest weight recorded is a basis for the gravest prognosis.

It is not possible in the scope of this paper to speak in detail of the recording of all the objective symptoms—the results of examination. It is of vital importance, of course, to keep records of the weight, pulse, temperature and respiration for each visit, as these symptoms are the best guides in prognosis and treatment.

It may be said that in an outline for history-taking such as has been given, there are entirely too many details for a practical man, who wishes to make a short cut to his diagnosis. We must remember, however, that careful study of every case of tuberculosis is of importance in the great struggle against the disease, and the assistance of every man is needed. Moreover, with a system carefully mapped out, a complete history of any case can be made in a half-hour.

The outline followed in this paper is in general the one adopted and now in process of development at the Henry Phipps Institute.

MEDICAL PROGRESS.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Pathology of the Suprarenal Glands.—G. Marchetti (*Virchow's Archiv*, Vol. 177, No. 2) has carefully studied the suprarenals in all autopsies during two years, and states his observations as follows: Accessory adrenals are most common along the anterior surface of the kidney or the hilus, or in the neighborhood of the spermatic artery. Displaced portions of the gland are more common, and always remain connected with the main gland by means of a pedicle of gland tissue or connective tissue. They consist chiefly of the zona fasciculata, but are often not altered in severe disease of the gland itself. Inclusions may also be encountered occasionally in other organs, as the ovary. Venous congestion is a frequent symptom, seen most distinctly at the junction between cortex and medulla. Punctiform hemorrhages are more common than larger ones, and are encountered in intoxication (eclampsic, jaundice) or infections (typhoid, pneumonia). Hypertrophy may be primary and total in valvular disease or compensatory and total where the second organ is destroyed or compensatory and partial, where a tumor, etc., has invaded one end. The medulla never participate in the process, but in the cortex the cells are closely set. The effects of trauma were well seen at the autopsy of a man who had been run over a year prior to his death: a large coagulum was found in the kidney region, which contained many fragments of the corresponding adrenal; those which had retained their capsule were hypertrophic and functionating, while the rest had undergone degeneration. Fatty infiltration is common in diseases of the heart and vessels, acute infectious disorders and cachetic individuals. The organs will increase in size and assume a bright yellow color on section. The only case of primary malignant tumor was a small carcinoma, detected accidentally in a man who

had died of pneumonia, while secondary nodules were found in cancers of pancreas and liver. The only benign tumors seen were a lipoma and a nodular hyperplasia of the medullary substance.

Paget's Disease of the Nipple.—K. ZIELER (*Virchow's Archiv*, Vol. 177, No. 2) does not believe that carcinoma secondary to eczema of the nipple starts in one case from the flat epithelium of the skin and in another from the cylindrical cells of the excretory ducts. It is useless to discuss this question any longer, since the development of malignant tissue necessitates the presence of an entirely new type of cells, originating either from the flat or cylindrical epithelium, or both. These cells result from degeneration of normal cells already present, and are especially common in eczema. Paget's cancer is thus closely allied to cancer secondary to a number of skin affections, such as leucoplakia, lupus, senile warts, etc. The disposition toward malignancy is, however, much greater than in the other affections.

Esophageal Glands.—In fully 70 per cent. of all cases J. SCHAFFER (*Virchow's Archiv*, Vol. 177, No. 2) found glands in the esophagus between the lower edge of the cricoid cartilage and the fifth tracheal ring resembling those which normally occur at the cardia. They lead to an excretory duct lined with high cylindrical epithelial, and where they end on the surface the esophagus may be clothed for some distance with cylindrical epithelium, giving rise to the so-called macroscopic erosions. Examination of young embryos shows that these areas are derived like the rest of the esophageae epithelium—from the original stratified non-ciliated cells, but for some reason they do not acquire the cilial characteristic for this period, and later on retain their cylindrical shape, while the rest of the cells undergo metaplasia and become converted into stratified cells.

Immunity Against Streptococci.—Investigations undertaken for the purpose of obtaining information as to the identity of the streptococci found in cow's milk and their relation to those found in the human organism, are now published by D. H. BERGEY (*Univ. Penn. Med. Bull.*, August, 1904). Goats and rabbits were treated with repeated increasing doses of certain streptococci isolated from cow's milk and from human beings, for periods of from three to nine months. The sera of these animals were then tested as to their agglutinating, protective and curative properties. It was found that the serum of animals immunized with cultures of streptococci acquires an agglutinating power for all varieties of streptococci, though the agglutination occurs in somewhat higher dilutions for the homologous culture than for those derived from other animals. The agglutination reaction affords no means of definitely differentiating between cultures of streptococci of human and animal origin. The serum of an animal immunized with cultures of streptococcus shows no definite bactericidal action against such organisms. The serum of animals immunized with cultures of streptococcus possesses some antitoxic effect against the toxic action of the filtrates of streptococcus cultures. The protective and curative properties of antistreptococcus sera as at present prepared are of very slight value, as indicated by animal experimentation. No great reliance can be placed on the statements of the efficacy of the antistreptococcus sera in the treatment of streptococcus infections, until animal experimentation gives us more definite insight into the mechanism of streptococcus infection and the manner in which the organism overcomes such infection.

Carcinoma of the Breast in a Cat.—Malignant tumors are not at all uncommon in domesticated animals, so that the finding of a typical cancer of the breast in a pregnant cat need not astonish. On examining the tumor microscopically, E. v. LEYDEN (*Zeitsch. f. klin. Med.*, Vol. 52, Nos. 5 and 6) was very much surprised to find the structure in every way the same as that of the corresponding growth in man, and, like it, many of the cells contained the so-called "birds-eye" inclusions, concerning whose nature there is so much dispute. The author still adheres firmly to his parasitic theory, and states that the inability to isolate, grow and inoculate the germ is not really an argument against its causal relation, since we are dealing, not with bacteria, but with protozoa, whose peculiarities are as yet little understood. It is impossible to explain the inclusions as merely evidences of cell-degeneration.

Constituents of the Blood Which Are Visible by Ultramicroscopical Methods.—By means of the ultramicroscope, recently devised, E. RÄHLMANN (*Deutsch. med. Woch.*, July 14, 1904) examined the secretions from diseased mucous membranes, and found, aside from the emigrated white cells, numerous bodies which were apparently derived from the epithelium and consisted of bits of protoplasm and nuclei. These had the property of changing both their shape and position. It was also found that certain changes occurred in the blood plasma as well as in the cells, which may serve to explain the rôle which the blood cells play in the metabolic processes of the organism. The conclusions are as follows: It is well known that a great number of red cells derived from the erythroblasts of the red bone-marrow and other places are constantly thrown into the circulation, and from the appearances seen in the ultramicroscope it seems proper to believe that the mature erythrocytes are broken up into very minute particles in order to make room for these accessions. The duty of these particles is to regulate metabolism within certain limits in every part of the body.

Leucocytes of Pus.—All forms of leucocytes could be detected by J. LEUCH'S (*Virchow's Archiv*, Vol. 177, No. 1) in pus examined by the eosinate of methylene blue stain. The neutrophile, polynuclear elements are most abundant and nucleus degeneration is very common; one type very frequently encountered is a neutrophile cell, with very dark, ball-shaped nuclei not giving evidences of chromatic network. Eosinophiles are frequently absent at first and plentiful later on, at a time when micro-organisms can also be detected. There does not seem to be any difference in acute or chronic pus, since eosinophiles occur in about 50 per cent. of each. They are generally better preserved than neutrophiles. Mast-cells are also frequent, but the granules rarely retain their original form, but generally appear coarse and irregular. Hymphocytes are often hard to distinguish from degenerated leucocytes or free, swollen nuclei and their protoplasm may be lighter or darker than the nuclei. Micro-organisms can be well demonstrated with the stain and are found free or within the neutrophiles. In most serous fluids examined and lymphocytes predominated, especially where tuberculosis was probable.

PHYSIOLOGY.

Relation of Blood Platelets to Coagulation.—The simplest way of obtaining blood platelets suspended in normal plasma for study is to let a drop of freshly-drawn blood fall upon a smooth piece of paraffin. The blood will not coagulate, but the red and white cells soon settle to the bottom, while the platelets will rise, so that if the upper surface of the drop be touched with a coverslip after twenty to thirty minutes, the latter may be obtained almost pure. If larger quantities are desired, a paraffined glass canula is inserted into the carotid, the blood drawn into a paraffined graduate and then allowed to settle in the

ice-chest. It is not probable that the platelets are formed from either red or white cells, since the latter show no signs of breaking up and retain their ameboid motion, and hemoglobin cannot be detected by the spectroscope. The theory that they are independent elements is still further strengthened by the fact that they may be observed circulating in the blood of the uninjured wings of bats. K. BURKER (*Münch. med. Woch.*, July 5, 1904), describes the bodies in question as follows: They are lentil-shaped and about three mikra in diameter, but occasionally present one or more processes so that they appear not unlike spermatogoa. They are furthermore colorless, possess ameboid motion and, with proper strains, show a central body. If examined in the fresh specimen, they do not retain their integrity very long, but soon break up and form the nuclei for long strands of fibrin. The coagulation of blood is influenced considerably by temperature and also varies much during the day, but is approximately the same for different individuals at the same temperature and same hour. There is a direct relation between the number of disintegrated platelets and the amount of fibrin and influences which retard the formation of the latter will also delay the breaking down of the cells. Various chemicals also influence both processes in the same way so that there can hardly be any doubt that they are closely related to each other. This is rendered still more likely by the fact that the weight of the platelets approximates the weight of the fibrin formed.

The Influence of Potassium Upon the Heart and Blood Vessels.—The intravenous injection of salts of potassium affects the heart and blood-vessels in a twofold manner. By direct action upon the circulating organs and by vasomotor action, according to L. BRAUN (*Pflüger's Archiv*, July 9, 1904). Only in the smaller doses do the potassium salts seem to have a stimulating action upon the cardiac muscle. Large doses of potassium damage the heart; removal of the potassium from the latter results in a speedy disappearance of the bad effects. Potassium has no vasodilator effects.

The Influence of Sea-Climate and Sea-Bathing Upon Metabolism.—The familiar experience that a stay at the seashore, together with a course of sea-baths, results in a stimulation of the bodily metabolism, is sustained by the experimental observations of A. LOEWY and F. MÜLLER (*Pflüger's Archiv*, July 9, 1904). An estimation of the changes in the oxygen consumption and the production of carbon dioxide was made. Individuals differ in the degree with which they react to the climate and baths of the sea. Three types may be distinguished: One shows no reaction to the climate and a slight reaction to the baths; the second type shows in the beginning a strong but afterward a diminishing reaction to the climatic factors, but displaying throughout a marked reaction to the baths; the third type shows a continued reaction to both factors. Moreover, the results vary in the same individual. Thus, west winds and an increased force of the waves increase the body metabolism. The stimulation of metabolism would go hand in hand with the stimulation of appetite, digestion, and psychic functions. The former, as well as the latter, is of reflex origin, the stimuli being various physical factors, such as lower temperature, movements of the air, etc. One cannot, however, predict the manner or degree in which the individual will react to these stimuli. The increase in appetite and the increase in metabolism have nothing to do with each other; they arise independently, and may occur singly or coincidently.

The Resuscitation of the Cranial Cells.—The recent epoch-making experiments performed by Kuliabko, in causing the human heart to beat as late as forty-eight hours after the death of the body, might have aroused the hope that it would in time be possible to bring the dead back to life. The above observer, in commenting upon this subject, scouted this idea as vain and fruitless, in pointing out that death starts first of all in the delicate structures of the central nervous system, and that it would be necessary to revive the latter before we could even consider the possibility of starting again the bodily machinery. An experimental investigation of the changes that accompany the death of the cerebral centers was made by F. MÜLLER and A. OTT, (*Pflüger's Archiv*, July 9, 1904). The authors endeavored to determine whether one is justified in maintaining the conception of the excessive sensitiveness of the gray matter to a cessation of the circulation of the blood, and whether it might not be possible, by means of a renewed and artificial circulation, in restoring the oxygen supply and removing the accumulation of waste-matters, to bring back the functional activity of the cranial cells. Nissl's method has revealed profound changes in the structure of nerve-cells even before death in animals slightly wounded. The researches of the authors show that immediately upon the cessation of the flow of blood to the brain, substances reacting acid to litmus-paper are quickly formed. The renewal of the circulation by means of a warm solution similar in composition to blood-serum results in no restoration of cervical activity, even though oxygen-starvation or an accumulation of metabolic products be guarded against.

MEDICINE.

Polymyositis and Polyneuritis in Measles.—The first case reported by W. JESSEN (*Berl. klin. Woch.*, August 8, 1904), deals with a woman of thirty-two years, who, ten days after the breaking out of an attack of measles, developed a diffuse painful swelling of the muscles, accompanied by edema. There was no enlargement of the spleen and the mucous membranes remained intact. A recovery came about very slowly. A polyneuritis after measles has thus far only been observed in two cases, to which E. EDEN (same journal), adds a third. A girl of sixteen years developed otitis media and bronchopneumonia as sequela to measles. She also presented hyperesthesia of the skin and tenderness on pressure along the various nerve trunks. The symptoms gradually subsided and were attributed to the measles as no other cause could be found for their appearance.

Diabetes Insipidus Treated by Strychnine Injections.—In the case reported the patient, a man of forty-nine years, developed diabetes after a fall which resulted in a severe shock to the nervous system. His previous health had been excellent. B. LEICK (*Deutsch. med. Woch.*, August 11, 1904), states that he tried various methods of treatment without success, until he began the injection of strychnine, as recommended by Feilchenfeld. The nitrate was given in daily quantities of from 0.0025 to 0.005 gms. for twenty days. The urine, which had amounted to 8,000 c.c., continued to steadily decrease in amount. The drug had to be stopped at the end of twenty days, on acount of the symptoms of intoxication, but the urine continued to decrease in amount down to 2,400 c.c. The patient's general condition also improved and at the end of four

weeks the urine was about 2,000 c.c. daily and the man was practically cured. No explanation of the action of the drug in this case is offered by the author.

Treatment of Chronic Colitis.—It is the opinion of J. SHOUP (*Am. Med.*, August 27, 1904), that the various types of chronic colitis are simply different stages of the same disease and may all be treated in a similar manner. Most of these cases occur in women and are accompanied by gastropsis, enteroptosis or nephroptosis. SHOUP believes that the condition is due to the entrance into the intestine of improperly prepared chyme, which by causing irritation and inflammation, finally brings on a chronic colitis. Where a ptosis of the internal organs is present, he overcomes this by supporting them with a corset, put on while the patient is lying down and which is laced from below upward. The treatment is reviewed as follows: The attack of pain which precedes the passage of mucous may be relieved by a hypodermic of morphine and atropine. Thorough evacuation of the bowels is secured by large doses of castor oil and high enemas of oil or alkaline solutions. Diet must be selected for the individual case, after a chemical examination of the stomach contents has been made. Digestion must be assisted and fermentation allayed. The bowels may be kept open by oils given by mouth, which act both as laxatives and lubricants. When necessary, astringent enemas may also be given. Sufficient rest is important, especially after meals, and, when practical, a change of air and scene is useful.

PEDIATRICS.

The Absorption of Fats in Infants.—An experimental investigation of the varying capacities of the absorption of fats in the infantile intestine was made by P. NOBÉCOURT (*Rev. Mens. des Maladies de l' Enf.*, August, 1904). The amount of fat absorbed is found by taking the difference between the amount taken in with the food and the amount found in the feces. In this way may be obtained the coefficient of absorption. It is necessary, however, to take into account the quantity of fat ingested, for, in fact, if the infant take very little fat, nearly all of it may be absorbed, while, on the other hand, if a great deal is ingested, a large amount will be found in the feces, even though the digestive and absorptive powers may be quite marked. In general, healthy, breast-fed infants have a very marked absorptive capacity for fats, even though they be permaturely born. A more or less constant impairment of this capacity is found in weak, dyspeptic infants, in infants sick with intestinal or pulmonary infections, in cases of myxedema. In convalescents from measles the absorption of fats is normal. In determining the kind of food the infant should have, it is necessary to take account of its fatty absorption coefficient. In infants who ingest a quantity of fat too great in proportion to the amount absorbed, it is necessary to diminish if not the quantity of milk, at least the quantity of fat. In certain cases skimmed milk or buttermilk produces excellent results.

The Significance of Bacteriological Methods in the Diagnosis of Diphtheria.—Most practising physicians have encountered cases of mild sore throat in children, looking not at all like diphtheria, and yet bacteriological examination revealed the presence of the diphtheria bacillus. The question would then arise. Is it a case of diphtheria, or of ordinary tonsillitis, the Klebs-Löffler bacillus being present, as it is in many normal throats. A critical study of the entire subject of the bacterial diagnosis of diphtheria is made by B. CZERNO-SCHWARZ (*Arch. of Kinderheilk.*, Vol. 39, Nos. 1 to 3), with the following conclusions: Of undoubted value is the negative result in the repeated investigation for the Klebs-Löffler bacillus. The bacteriological method has revealed that even membranous anginas, membranous larygitides and croup may be non-diphtheritic. Rauchfuss, in 1894, published a learned array of such cases. Since that time this fact has received general acceptance. The author observed, among others, seven cases of laryngeal stenosis with a clean throat (which cases always arouse the suspicion of diphtheria), in which repeated examination did not reveal the presence of the Klebs-Löffler bacillus. The author is equally positive as regards the positive result of bacteriological examination, in cases in which the clinical picture is one of diphtheria. The author agrees with Schabad that hardly any one at this date would fail to make the diagnosis of diphtheria if the clinical picture is of this disease and if the culture is positive. On the other hand, in all those remaining cases in which the clinical picture and the positive culture do not agree, one has no certain criterion upon which to base a diagnosis. In all these cases a diagnosis of diphtheria should be made, at least until the time when bacterial diagnosis shall have made further progress, not alone upon the subject of the presence of the Klebs-Löffler bacillus, but also in the ability to recognize the intoxication of the organism with the diphtheria poison. In order to prevent misunderstanding, the author adds that he has treated of the scientific aspect of the diagnosis of diphtheria, and that he is not opposed to the practical measures taken when the Klebs-Löffler bacilli are discovered in the throats of patients. Those whose throats contain these bacilli frequently develop the disease later on, or else infect others with the disease, and for these reasons prophylactic measures are justified, without respect to the diagnosis of the primary disease or absence of disease in the throat, in which latter case the bacilli may be merely accidental parasites.

Treatment of Hydrocephalus.—A case of the chronic internal type is reported by H LÖWENBURG (*Am. Med.*, Aug. 6, 1904), which he treated by lumbar puncture. The child, about twenty months old, had from 50 to 60 c.c. of cerebrospinal fluid withdrawn by puncture once a week for a period of two months. The child improved mentally and physically and the head also became reduced in size. Death was finally due to pneumonia following measles. The writer considers that the following conditions must be present in each case before lumbar puncture can be practised: Free communication must exist between the ventricles and the subdural spinal space, which is shown by the fact that after the puncture, the fontanelle becomes scaphoid. The head must be compressible. The bones must be flexible and there must be no evidence of ossification in the fontanelle or the sutures. Ossification is usually well advanced after the second year, and, therefore, treatment must be instituted before this period. Lumbar puncture is preferable to direct tapping of the ventricles, as there is an entire absence of all danger of the untoward complications following the latter.

OBSTETRICS AND GYNECOLOGY.

Secondary Abdominal Pregnancy.—Two interesting cases are reported by F. PRUMANN, (*Zeitschr. f. Geb. u. Gyn.*, Vol. 52, No. 2). In one an intraligamentous pregnancy developed from the left tube,

which ruptured, but the fetus continued to develop in the abdominal cavity. When two weeks over time the woman was operated upon and a living child extracted. The placenta was adherent to and derived its nourishment from the intestines. The hemorrhage prohibited its removal and it was sewed into the abdominal wound. The woman died shortly after in collapse. The other case developed from an intestinal pregnancy in which a seven-months' fetus remained in the abdominal cavity for a year before operation. It had grown fast to the fundus uteri. The woman recovered. In this instance the fetus continued to grow, although the placenta remained at the original interstitial attachment.

Hemorrhage in Labor.—A sudden severe hemorrhage is the most alarming condition that the obstetrician has to meet. Accidental hemorrhage is due to premature separation of the normally implanted placenta. In considering its etiology, J. Rosenberg (*Am. Jour. Obstet.*, August, 1904), mentions exophthalmic goiter as a predisposing cause. Traumatism, emotion, hydramnios, multiple pregnancy and shortness of the cord may all produce premature separation of the placenta, but syphilis, nephritis and uterine tumors are the most important factors. The symptoms are those of shock from loss of blood, abdominal pain, abnormally large uterus, bulging and tenderness over the part corresponding to the placental site. The absence of placenta previa confirms the diagnosis. The prognosis for mother and child is bad in concealed hemorrhage; in external hemorrhage the mother's chances are better. The treatment should be rapid delivery. If the soft parts are dilatable, version, forceps or craniotomy may be resorted to. If the cervix is intact it may be incised or dilated with the fingers, metal dilators or Barnes' bag. "Conservative treatment" helps the woman bleed to death. A disease endometrium and uterine subinvolution predispose to placenta previa. The main symptom is hemorrhage, which is rare before the middle of the seventh month and may not appear before the end of pregnancy. The diagnosis depends upon the recognition of the spongy placental tissue. The treatment should aim to minimize the loss of blood and deliver in the interest of the mother. If the cervix is not dilated a firm gauze tamponade will usually arrest the bleeding and bring on labor pains. In marginal implantation, when the cervix will admit a finger, rupture of the membranes is advocated. A version should be done and a foot brought down out of the vulva; if the implantation is central and the hemorrhage profuse, the breech should be left in utero to act as a tampon and dilating wedge. A child should never be forcibly extracted through a partially dilated cervix. Postpartum hemorrhage may follow accidental hemorrhage and placenta pervia caused by uterine overdistention, general anemia and muscular relaxation. A hemorrhage before delivery of the placenta is due to a partially separated placenta usually ascribable to undue interference in the third stage of labor. The treatment consists in emptying the uterus by Credé's method, using the hand, if necessary. True post partum hemorrhage occurs after expulsion of the placenta and is due to atony of the uterine muscle. If the blood is bright red and the uterus contracted the source is a torn cervix, which should be repaired at once. If the uterus is large and buggy, the blood dark and clotted, the hemorrhage is from the placental site and calls for the following treatment: Massage of the uterus, injection of ergot, compression of the abdominal aorta, hot or cold intra-uterine douches with vinegar. If these measures fail, the uterus and cervix should be packed with gauze. Enteroclysis and hypodermoclysis should be resorted to, as may be necessary; intravenous infusion should be reserved for desperate cases. Raising the foot of the bed, auto-infusion, stimulants, hot cloths on chest and abdomen, ice-bag over uterus, all have value. Intra-uterine packing should be removed in twenty-four hours and followed by hot irrigations.

THERAPEUTICS.

Formaldehyde in Milk.—The germicidal action of this substance in milk and its gradual disappearance from the latter has been made the subject of an experimental study by D. Rivas (*Univ. Penn. Med. Bull.*, August, 1904). He found that small amounts (1:10,000 to 1:100,000) of formaldehyde added to the milk will gradually disappear from such milk in the course of twenty-four to thirty-six hours. This amount of formaldehyde exerts some detrimental influence upon the activities of the bacteria in the milk, as shown by the relatively lower bacterial content of such sample when compared with control samples. Samples of milk containing such small amounts of formaldehyde acidify more slowly, and do not coagulate as early as control samples. The fact that samples of market milk show unusually good keeping qualities and yet apparently do not contain formaldehyde, should at once raise suspicion that these samples may have had formaldehyde added to them, and that in time the formaldehyde has disappeared from such milk.

Therapeutic Value of Dreyer's Method of Phototherapy.—This is based on the assumption that the injection into the tissues of a solution of erythrosin renders them more sensitive to the action of the red rays and permits the latter to penetrate to a greater depth than ordinarily. B. Spiethof (*Berl. klin. Woch.*, July 18, 1904) reports the results of his clinical experience with this method in six cases of lupus, three of which had been treated rather unsuccessfully with the ordinary Finsen rays. The others had not been treated at all. He found that the reaction after exposure to the Finsen rays is much more intense where it has been preceded by an injection of the erythrosin than where this has been omitted. Animal experiments showed that the latter substance itself caused a reaction when used in 1 per cent. solution, although none was noticed with the use of the 0.25 per cent. solution. The effects obtained are therefore a combination of two factors—the rays and the erythrosin. The author had practically negative results with the method and no better effects were obtained in those cases where the injections were used than in those where they were omitted. He does not feel encouraged to ascribe much practical value to the procedure.

Treatment of Hemorrhoids.—According to D. Proebsting (*Zeitsch. f. klin. Med.*, Vol. 53) all the symptoms of piles are due to the fact that the lower rectum is never completely emptied, but that small masses of feces remain behind, which dry out to hard scybalous masses and set up a spasm of the sphincter. To avoid this spsam, 80 to 100 grams of cold water should be injected into the rectum after every defecation. When cold water is contra-indicated owing to bladder trouble, etc., lukewarm water may be employed. If the spasm and its concomitant symptoms, such as itching, are already present, lukewarm water should always be preferred, since cold water will increase the spasm.

Adrenalin in Hemophilia.—The admixture of this drug with ergotinine citrate has much to commend it. Ernest Francis (*Brit. Med. Jour.*, May 28, 1904) Chief

Medical Officer of Bengal Railway, recites the case of a male Hindoo Brahmin, thirty-two years of age, whom he was called to see for the purpose of controlling severe hemorrhage from the mouth, which having come on without apparent cause, had lasted for six hours. The patient presented the usual signs of partial exsanguination. The uvule was tremendously engorged 2½ inches in length and bleeding freely. Partly because of the necessity of hurrying as well as on account of the difficulty of getting a history from this wealthy high-class Hindoo, no delay was made, but the engorged organ was seized with the forceps and cut off. The patient died six days later from intestinal hemorrhage, but it is of interest to note that a hypodermic injection wound was immediately controlled by the use of adrenalin, and the hemorrhage from the wound in the pharynx, which because of the nature of the lesion was large, was also entirely stopped by the above-mentioned drugs.

Therapeutic Value of Lumbar Puncture.—Lumbar puncture is of great diagnostic value, for it will determine the presence of pus or of an excessive amount of serum, and it will also enable a bacteriological examination of the spinal contents. In therapeutics it is, however, more limited. T. WERTHEIMBER (*Münch. med. Woch.*, June 7, 1904) has seen the best results in serious meningitis, that peculiar disease of children, secondary to infectious diseases and characterized by hyperemia of the retina or choked disk, retention of urine, slow pulse and slight fever. Most cases will die suddenly after three to five months, unless the excessive cerebrospinal fluid is drawn off repeatedly. Recently good results have been seen in chlorosis; the severe headache and vomiting will stop here almost at once if 30 to 60 c.cm. of fluid are removed. The meningitis of children is also benefited and often cured.

Adrenalin in Pulmonary Hemorrhage.—It is well known that after the administration of this drug, the blood pressure increases. This increase is so considerable that it can readily be noted at the wrist. DUNCAN MACDONALD (*Brit. Med. Jour.*, May 28, 1904) recites the history of a case of a single male twenty-eight years of age, who four years ago developed the usual signs of pulmonary tuberculosis. After about four years he began to have severe hemorrhages, which were treated after the usual routine method. So far as the ultimate issue of the case goes, the adrenalin did no good, for fatal hemorrhage occurred one week after its administration was commenced. It did not, however, interfere with digestion, and if it did no good, it is certainly safe to assert that it did no harm.

Treatment of Hemorrhoids by Oscillatory Currents of High Tension.—The widely recognized fact that malignant change and growth is apt to take place as a result of chronic low-grade inflammation lends to the minor ills of the rectum an importance which they had not previously attained. T. J. BOKENHAM (*Lancet*, July 2, 1904) recites his experiences of Doumer's method for treating hemorrhoids and fissures by high-frequency currents. He cites that the method is quickly successful in healing fissures. It is valuable in relieving pruritis ani. It is also valuable in the treatment of internal and external hemorrhoids, particularly in their early stages, where extensive thickening has not taken place. The author has used it in over 100 cases of rectal lesions. The exact form of the electrode is probably of very small importance, the point being that it must be long enough to pass through both sphincters and with such diameter that its surface will touch every area of the parts. A vacuum electrode of such high vacuum that there are produced in it abundant X-rays is less unpleasant to the patient and has less therapeutic action. The duration of each application should be about fifteen minutes, and in many cases five minutes is better. The results leave much to be desired in the matter of effecting permanent cures, but they are probably, in the opinion of the author, superior to any other form of treatment except operation.

Sinusoidal Current and Circulatory Organs.—It has been alleged that fresh-water baths, through which the sinusoidal alternating electric current is conducted, have proved of value in cases of cardiac debility and have cured cases of dilatation with muscular weakness. PAUL C. FRANGE (*Dublin Jour. Med. Sci.*, July, 1904) has investigated the action of such baths on the volume and frequency of the pulse, the outline of the heart and on blood pressure. On an average the pulse rate decreased after the bath by five beats per minute, the blood pressure increased by 8 mm. of mercury. In some cases a single electric bath was sufficient to remove a certain amount of cardiac dilatation. Such baths were recommended as a valuable adjunct to, but not in lieu of, the effervescent brine baths of Nauheim.

Alkaloids of Jaborandi.—A research into the physiological action of the alkaloids contained in jaborandi leaves was made by C. R. MARSHALL (*Jour. of Physiol.*, May 3, 1904) with the following results: Jaborandi leaves contain three alkaloids—pilocarpine, isopilocarpine and pilocarpine. Isopilocarpine only occurs in small quantities, and pilocarpine only in small amounts in *Pilocarpus jaborandi Holmes*. No substance corresponding to jaborini has been found in the leaves, either chemically or physiologically; but a substance possessing an atropine-like action is present in the jaborine of Merch, which, however, consists mainly of pilocarpine or isopilocarpine. Pilocarpine eats up the so-called nerve-endings in the heart, and its action is comparable in nearly all points with that obtained by electrical stimulation of the vagus. A small dose of atropine is able to counteract for a definite time an excessive amount of pilocarpine. Small doses of pilocarpine increase the sensitiveness of the vagus to electrical stimulation. Large doses, if injected during electrical stimulation of the vagus, are practically without action. The antagonism of pilocarpine and antropine is physiological. Isopilocarpine acts like a weak pilocarpine. In efficient doses it is about six times weaker. In large doses it is about twenty times weaker. Pilocarpidine is still weaker than isopilocarpine. The homopilopic portion of the pilocarpine molecule acts at least as an interacting to haptophore group. Solutions containing the hydroxy-acid corresponding to the lactone-pilocarpine are inactive. The influence of the glyoscaline part of the molecule has not yet been determined.

Action of Strophanthus.—In summing up the pharmacological action of strophanthus, G. GÜNTHER (*Therap. Monatshft*, June, 1904) states that this drug is a pure heart-muscle poison, which kills by bringing about diastolic cessation of heart-action. Intoxication gives rise to characteristic changes in pulse and blood-pressure which differ from those caused by digitalis, mainly in the absence of vagus irritation. Strophanthus also brings about vascular contraction, but less so than digitalis, and it seems to have a specific action upon the vomiting center. The only antidote is artificial respiration; neither morphine nor chloralhydrate possess any efficacy.

Maretin, A New Antipyretic.—Very favorable reports on maretin, as an antipyretic in the fever of consumptives, is contained in a short article by D. ELKAN (*Münch. med. Woch.*, July 26, 1904). He finds that the drug depresses the temperature slowly without causing collapse or excessive perspiration and without in any way influencing respiration,

digestion or circulation. Bad after-effects or cumulative action were never observed. The drug is cheaper than pyramidon and may be given in doses of 0.5 grams once daily, or half this amount twice daily. It is only slightly soluble in the usual solvents.

Morphine in Heart Disease.—There is no reason to look upon morphine in its usual therapeutic doses as heart-poison and to consider it contra-indicated where a heart lesion is present. K. Grassmann (*Münch. med. Woch.*, November 28, 1904), states that sudden death may occur after the use of morphine, but that this is just as unavoidable as collapse in chloroform necrosin. Great care is, however, necessary where respiratory complications exist, especially if these are acute, and also in acute processes of the endo and myocardium. Morphine can be employed without fear in purely nervous disturbances, especially in nervous angina pectoris and in organic angina small doses are indicated. The drug should never be withheld in chronic cardiac dyspnea, and in excited and sleepless patients it plays an important rôle as sedative before digitalis is begun.

NEUROLOGY AND PSYCHIATRY.

The Neuron Theory.—Recent research has shown, according to A. Bethe (*Deut. med. Woch.*, August 11, 1904), that the neuron theory, as first advanced, no longer holds. There are certain facts which have been contradicted and considerable doubt exists regarding the validity of others. It is now stated that the neuron can no longer be looked upon as cell unit, because the latter embryological and historical findings show that at least the axis cylinder processes of peripheral nerves are of multicellular origin. The demonstration of autogenous regeneration has apparently also confirmed this view. It is likely that, in addition to the neuron complexes, there are other nerve elements which are independent of the former. In every nerve plexus, in both vertebrate and invertebrate animals, the cells are connected by well marked anastomoses. In the central nervous system of snails and crustaceans, fibrillary connections between distinct neurons have been demonstrated with certainty. In vertebrates such relations have not been fully proved, but there is sufficient at hand to warrant the belief that they are probably present. Bethe claims that the neurons do not represent trophic, or even functional units. He thinks that the name may be retained and applied to the complex of ganglion cell, dendrites and cylinder process, as it furnishes an excellent conception for a teaching scheme.

The Social Causes of Alcoholism.—A statistical study of the various social causes of alcoholism was made by W. C. Sullivan (*Jour. of Mental Sci.*, July, 1904). It is necessary to distinguish two opposed types of drinking, namely, the drinking associated with conditions of relative luxury (convivial drinking), and the drinking associated with conditions of relative misery, the result of bad industrial circumstances. Convivial drinking often leads to drunkenness, but does not tend very much to chronic alcoholism. Industrial drinking, while leading also, though less immediately, to drunkenness, tends rapidly and fatally to chronic intoxication. From a statistical point of view, while chronic alcoholism always implies the existence of drunkenness, the latter by no means implies the existence of chronic alcoholism. In England this divergence is best seen in the prosperous mining districts, which by reason of their prosperity are at once more drunken, but less alcoholic, than any other part of the country. The graver social evils that are in any important degree caused by alcohol are related to the chronic intoxication, and are, therefore, mainly due to industrial drinking. While educational, religious and similar influences can control the excesses of convivial drinking, they have but little action on industrial alcoholism, which can only be checked by raising the standard of living, and, in a minor degree, by such methods as restricting the facilities for obtaining alcohol during work hours, providing hygienic substitutes, and so forth.

SURGERY.

Clinical Experience with Renal Decapsulation.—This method of treating certain cases of Bright's disease, as suggested by Edebohls, was tried by P. Rosenstein (*Deut. med. Woch.*, July 28, 1904), in a series of six cases. The general result was unsatisfactory. One patient died from the operation, one grew worse, two were not influenced at all, and the remaining two showed some improvement. Rosenstein believes that the favorable results secured by Edebohls were due to the fact that these were not true cases of nephritis, but were merely inflammatory processes brought about by an abnormal mobility of the kidney. Moreover, among the cases reported by Edebohls were nine which were designated as presenting a unilateral Bright's, which, Rosenstein claims, does not exist, but that the process is always bilateral. The mortality which attends renal decapsulation 26 per cent. is considered by Rosenstein to label the operation as a very dangerous one. He affirms that cure has not resulted in an undoubted case of Bright's from this operation. The following improvements were noted in his two cases: Objectively, in one the slight edema disappeared, but there was no change in the albuminuria; subjectively, in another case, the headache and visual symptoms which were present before operation disappeared.

Fibromyxosarcoma of the Sacrum Treated by Cataphoresis.—The patient, a woman of twent-six years, presented a hard growth in the posterior portion of the pelvis, for which operation had been attempted and given up. There was a history of two difficult labors previous to the appearance of the tumor. G. B. Massey (*Am. Med.*, August 27, 1904) reports the case and the result of his method of treatment. The patient was anesthetized and placed on a negative pad on a cot. An incision was made over the upper part of the coccyx and a sharp pointed zinc-mercury electrode was introduced and thrust through the healthy tissues about the coccyx into the tumor, so as to avoid injuring the sphincter ani. A current of 1,600 milliampères was slowly turned on, which developed the ionized chemicals by electrolytic destruction of the anode and dispersed them radically from the electrode, thus necrosing and sterilizing an increased area of skin, subcutaneous tissue and malignant growth. The current was used for three hours, and the necrotic area covered three inches. Twenty-one days later three of the coccygeal bones and one-half of the tumor sloughed out through the opening. A second application was made a month later, 1,200 milliampères being applied for two hours, and sixteen days later the remainder of the mass came away, followed by the rest of the coccyx. The patient made a good recovery, and seven months after operation presented a useful rectum and only a small sinus. The histological examination showed the tumor to be a fibromyxosarcoma.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 17, 1904.

AN OUNCE OF PREVENTION AND THE POUND OF CURE.

THE echoes of the requisition for a hundred thousand square yards of wire gauze mosquito netting, by the Commissioners of the Panama Canal, are still reverberating through the daily press. And yet a million square yards would not be too much (as Dixey said about the tidies), for mosquito netting, when we consider what great practical good its use will accomplish. For the bed of the forty-seven miles of the projected canal will be scarcely a bed of roses, while the canal itself will resemble anything but the beauteous stream that meandered through the Garden of Eden. Now, if any one thing has been definitely proved by the experiments of late years it is that both malaria and yellow fever are disseminated through the agency of mosquitoes, and the voices of both the *Stegomyia fasciata* and the *Anopheles* are particularly loud in that particular land. There will be, of course, much excavation of fresh earth, and in the rainy season the results will be the formation of innumerable marshy pools where the mosquitoes will propagate in vast numbers and then carry the seeds of these diseases from one encampment to another.

That the death rate will be enormous under any circumstances is evident, and any efforts of those in charge of the undertaking to lessen it from the fearful height that it attained under the régime of de Lesseps, should be applauded and encouraged by the press and not be hampered and curtailed by the cry of petty economy, or ridiculed from that crass want of knowledge that seems to be characteristic of the daily newspaper when dealing with scientific subjects.

There are already some dozens of barracks built by the former company within easy distance of each other along the banks of the proposed canal, and it is now the intention of those in charge to protect all the windows and doors of these quarters with netting, and to see particularly that the latrines of the men are so guarded that the mosquitoes will be unable to enter. In order to accomplish this the gauze is to completely envelop the entire structure, as one house might be built within another. As to the laborers themselves, it is more than a difficult problem to handle. The last lot were the veriest scum of the earth; the refuse of all nations, worn and broken down by ill-health. Racked by fever and dissipation they would have been vile by comparison with much more pleasing prospects than can be found anywhere on the Isthmus of Panama. Always mutinous, constantly fighting with each other, and endowed with that cheerful feeling of hostility toward strangers, that was so characteristic of the early days of Marblehead and which is now pathognomonic of Port Said, the wonder is, not that they died hourly, but that the majority of them succeeded in living at all.

The only possible solution of the problem would be the introduction of the Chinese coolie, who is the very best type of laborer for that particular form of work, that the world has ever produced. But the immigration laws in regard to the Mongolian are very strict, as the American workingman, and through him his Congressman, prefer to be ruined by anything rather than "Chinese cheap labor," and any efforts to influence Congress on the eve of a general election would be more than futile. They might, it is true, be landed in Mexico, which is still open to the Chinese, or be imported at the other end of the canal at Panama, but the labor unions have discovered this and the cry has already been raised that the canal strip is American territory, under the American flag, so that the labor-seeking spade of poor John will hardly turn the soil of "an

earthy to-day, nor yet of a dusty to-morrow." All this does not seem to hold out much hope for a great improvement in the personnel of the laboring force, and the reign of the beach-comber and cutthroat of the past will probably, like history, repeat itself, but with the sanitary restrictions, discipline and improved commissariat of the United States Government behind them it will certainly be in the power of the Commissioners to greatly ameliorate the condition of the working gangs.

Then, too, there is no cloud without its silver lining and the darkest hour is followed by the rising dawn, so that the proposition of Mr. William Growley, of Toledo, will not only add strength to the hearts of those delving in the Isthmian wilds, but will carry balm and comfort to the cherished ones at home. For with it comes the assurance that they will again behold the faces that they knew and loved, and that the grave has been robbed by him of its victim, while death itself has lost its sting. That Mr. Growley will be able to accomplish all that his friend Mr. Calloway states in his behalf we have no doubt. There is a certain straightforward-businesslike method in his communication, that is calculated to inspire confidence in his mercantile integrity, and though his postscript perhaps smacks overmuch of "graft," yet a great deal can be excused in the enthusiasm of a friend, which may not be politic, but is undoubtedly sincere. The letter, which was delivered to a newspaper correspondent, supposed to be in touch with the members of the Commission, is as follows:

Dear Jimmy: This will be presented to you by my old friend William Growley. We call him "Bill" here in Toledo and I want you to go to the front and hustle for him. Perhaps you remember Bill's place in Summit Street? He has a good business in the undertaking line and desires to extend it. In other words, Growley thinks that there is a chance for him on the Isthmus. He has heard that men die there by the hundred every day. What he wants is the contract to bury those who fall by the wayside, so to speak. I heard you speak of Admiral Walker when you were here last summer and I told Bill that you were just the chap to help him, and I know you will—for my sake. Go to the front, old man, and see if you can't land this contract for Growley. He is a good fellow every way and can get all the necessary testimonials.

The boys here are all well and join me in sending you our best wishes. Yours, as ever,

Jack Calloway.

P. S.—Growley is an A1 embalmer, and, if he gets the contract, will fix up the friends of the Commission who happen to die on the Isthmus in bully shape to send home. J. C.

To all of this we can only say "Amen." J. C. is evidently not an angel, as he has butted in where they proverbially fear to tread. But while we wish him well, we most sincerely trust that if his friend secures the contract that he will not be called on to return his favors professionally to the members of the Commission. They are, as a rule, portly dignified gentlemen, who have not for many years traveled on their "shape." So we earnestly hope that the only necessity they will encounter for "cracked ice" and "preserving fluid" will be that little, which St. Timothy teaches us, it is well to use for the stomach's sake. As to Mr. Growley, personally we know him not, beyond his name, which seems to indicate that God is good to him, but from his enterprise and push we are inclined to believe that he must be a lineal descendant from that good old Irish paragon, of whom Florence, the comedian, used to sing to us, so many years ago: "Begorra! Mister Growley, you're a d—d foine man."

HEPATIC DISEASE IN PREGNANCY.

One of the most interesting recent developments in that practically universal specialty of obstetrics is the recognition of the fact that pregnancy seems to throw a special strain on the liver, which is not always well borne. It has been the custom to talk overmuch of kidney affections in the course of pregnancy. Some of these have been supposed to be merely functional, due to the extra work thrown upon the kidneys of performing the excretory function for two beings, especially under the unfavorable conditions of increased intra-abdominal pressure with consequent disturbance of circulation. These affections were thought to be completely recovered from, in most cases, and the significance of albumin during pregnancy has been one of the disputed points in urinary diseases. It has been recognized that if true kidney disease existed before pregnancy began there was serious danger of an exacerbation of the affection, with resultant damage to the organs and often a fatal result. In general, however, too much emphasis has been thrown upon renal disorder as the basis of many pathological conditions during pregnancy, for which no other adequate cause was apparent. It has been easy to make the kidney responsible and thus medical ignorance has been cloaked and unfortunately medical curiosity satisfied by expressions such as "the kidney of pregnancy," "renal congestion in pregnancy," and the like, where no direct connection between these conditions and the kidneys was traceable.

As the result of recent investigations the liver is to be made to share its burden of responsibility for serious health disturbances during pregnancy. The recognition twenty-five years ago of acute yellow atrophy of the liver as an accompaniment of pregnancy and the study of this disease threw some light on an important subject, but, unfortunately, it was concluded that this condition was very rare and therefore need not be much considered. In its extreme form there is no doubt that it is rare. In milder forms, however, it is probable that it exists much more frequently than has been thought and recent autopsies, both in Europe and America, show that certain cases of eclampsia, as well as cases of pernicious vomiting, which have proved fatal, exhibit degenerations of the liver substance not unlike the pathological changes in acute yellow atrophy.

The pathological picture which is nearest that of acute yellow atrophy is found in phosphorus poisoning. It is well known that this is due to the absorption of phosphorus into the circulation and its direct transportation through the portal system to the liver where it produces extensive fatty degeneration. If this fatty degeneration has continued for some days, there is an absorption of fatty material with a lessening of the size of the liver and the picture then resembles very closely that characteristic of acute yellow atrophy. Whether there is some extremely irritant substance absorbed from the digestive tract in the course of certain pregnancies which produces this tendency to fatty degeneration in the liver remains to be proved. It would seem, however, that the digestive tract must be held primarily responsible. The fact that pernicious vomiting should be one of the clinical manifestations of this hitherto unassociated group of affections appears to confirm the suspicion of digestive disturbance and the absorption of toxic substances from the digestive tract as a principal element in the etiology of these conditions.

It would not be strange if the carrying of certain of these intensely toxic substances to the kidneys should produce at least a functional derangement of their secretion. Phosphorus has almost as severe an action on the kidney as it has upon the liver. Even though the irritation were milder than that produced by phosphorus, the presence of albumin in the urine, of a certain amount of blood and of casts covered with cellular detritus would be within the boundaries of rational anticipation. It has been well recognized for some time that no dependence could be placed on any indications of the approaching development of eclampsia that might be derived from the amount of albumin in the urine. In fact, the whole etiology of eclampsia, notwithstanding all the work that has been devoted to it, has remained shrouded in obscurity. It is to be hoped that the present line of investigation will prove more fruitful of lasting results than have previous studies. It is extremely suggestive to find that a number of conditions in pregnancy, hitherto thought to be quite unrelated, are perhaps due to modifications of the same set of pathological changes and that all of them are associated with digestive disturbances rather than with intractable organic lesions.

THE URINARY DISTURBANCES IN LOCOMOTOR ATAXIA.

The victims of tabes dorsalis are frequently subject to bladder disturbances; these commence and evolute silently and the ultimate outcome is distention of the bladder. This subject has been ably discussed in a paper by Desoros, read at the Société de Thérapeutique de Paris, February 24, 1904.

An early diagnosis is of the greatest necessity in these cases. The first symptom is a peculiar *hesitation* at the commencement of micturition. It is a kind of timidity of the bladder, a urinary stuttering, which begins by the passage of a few drops of urine, then ceases, and afterward begins again. The jet may retain its full strength for a considerable time, but at last the urine falls vertically to the ground, drop by drop.

Beside these common symptoms, two others of much greater diagnostic weight enter upon the scene; (1) sudden arrest of the flow without giving rise to any pain to the patient or to that sensation of contact so readily perceived in cases of calculous obstruction; (2) the impossibility to expel the urine, which effort is followed by an involuntary evacuation. The patient cannot micturate when he desires and he voids urine when he does not wish, and he is surprised to find his clothes suddenly wet.

Sensory phenomena then follow. Shooting pain in the region of the bladder, extending down the penis or urethra, is not uncommon, but attacks of cystalgia and vesical neuralgia of great intensity occur, being increased by micturition, which in its turn is made more frequent from these attacks.

In other cases, which are the most usual, the patient complains of a vague sensation, with frequent and impeded micturition and finally pain. All this is simply the ordinary clinical picture of an irritable bladder, which is met with in the beginning of tuberculous cystitis just as in ataxia.

Incontinence of urine is the symptom which most forcibly attracts the patient's attention and is due to irritability of the bladder; it should be considered as a false incontinence because it is produced by frequent and imperious desire to empty the bladder. The patient is unexpectedly seized and not having the time to control himself, the act is accomplished in his clothes.

In other cases the incontinence is caused by a paralysis of the sphincter, and, as has been pointed out, it may follow fruitless efforts at micturition. In the majority of cases, however, there is another cause, namely, incontinence by retention, and patients may very rapidly reach this stage.

To make a diagnosis, one should take locomotor ataxia into consideration in the first place, for it is quite frequent to see the urinary apparatus attacked the first of all, and it may present the only symptoms for some time. A general examination of the patient will give one the key to the situation and, as far as local examination goes, palpation of the hypogastrium and digital exploration of the rectum will suffice, which allows one to appreciate the condition of the prostate and to map out the distention of the bladder. The catheter should only be used as a last resort, because the bladder in ataxia is far more readily infected than a normal one.

The urinary disturbances of tabes are usually mistaken for those set up by urethral stricture or hypertrophy of the prostate, as well as cystitis and infections of the bladder. The condition of the urine, the use of the bougie à boule, which shows the condition of the urethra without entering the prostatic portion or the bladder, the advanced age of prostatic subjects, the increase of the symptoms at night, etc., will settle all doubt as to the nature of the affection as far as the prostate is concerned.

A mercurial treatment should be begun at the same time as the local treatment. The latter has two indications to fulfill, namely to prevent retention from taking place at the commencement and at a later date to prevent ascending lesions. If the bladder empties itself the catheter should not be employed, but when this is not the case the urine should be drawn off at regular intervals and asepsis must be absolutely perfect, especially when the bladder is distended and presents a soil in every way prepared for infection. The urine should be drawn slowly, as when dealing with prostatic enlargement, because this is the best way of preventing the occurrence of severe hemorrhage, which might otherwise arise.

If the bladder is primarily infected, or should it become so, a few irrigations with one of the ordinary antiseptics are indicated, but, above all, one must be sure to empty the bladder first.

When the treatment is well conducted, not only will the retention diminish, but the bladder is quite susceptible of regaining a certain degree of contractility. Intravesical electrization is of little value and is very prone to produce a hyperemia of the bladder walls, a condition that should always be avoided.

ECHOES AND NEWS.

NEW YORK.

Dr. Cabot's Appointment.—Dr. Follen Cabot, Jr., has been appointed Visiting Surgeon to the City (Charity) Hospital, New York. He will assume the duties of his position in the near future.

Typhoid Situation.—The Department of Health reports 146 cases of typhoid fever for the week ending September 10, with 21 resulting deaths.

Inspector of Contagious Diseases in the Bronx.—Commissioner Darlington has announced the creation of the office of Chief Inspector of Contagious Diseases in the Bronx, which will be filled by Dr. Charles F. Spencer, of 1124 Tinton Avenue. The Commissioner said that on account of the rapid increase of population above the Harlem the work had increased so that the present Sanitary Inspector was unable to keep up with it. The new office will be at the headquarters of the Health Department, One Hundred and Sixty-eighth Street and Franklin Avenue.

War on Trachoma.—With the opening of the public schools the Department of Health will renew its active struggle against trachoma. Inspectors will visit every building and every room as soon as possible after the regular work begins, and the eyes of every child will be examined for traces of the disease, which is gradually beginning to give way under the continued assaults of the department. Children suffering from trachoma will be kept from school until they have undergone an operation or had appropriate treatment. The department will perform the necessary operation and administer treatment without charge. A certificate from any reputable physician that a child has begun treatment will obtain readmission. The school children who are to undergo operation will have to wait their turn at the new trachoma hospital the department has opened at West One Hundred and Sixteenth Street and Pleasant Avenue. From five to six operations a day is the capacity of the hospital. Treatment will be given at this place and at a small building on the grounds of Gouverneur Hospital, on the East Side. It is believed that this inspection will show a great falling off in the number of trachoma cases. After the

schools are well settled and the trachoma examination completed, it is proposed to test the eyes of the school children for defective vision.

The Physical Test.—Grand Chief Warren S. Stone, of the National Brotherhood of Locomotive Engineers, has not let one thing be forgotten. Recently he was quoted as saying: "There was some talk, too, over the physical examinations the men don't like. We object to the present system, the standard railway test, and want the practical test—that is, we want men to be subjected on a railroad to the test of color. Let a man be taken out in the open and asked to test colors and semaphores. Men can do that and stand the test who couldn't arrange a skein of sixteen bits of yarn from light to dark. But that will be fixed up by the arrangement in the future. The "standard railway test" to find out whether a man is color blind was designed by expert oculists as the safest and surest method of getting at the truth about a man's eyesight. It is a hard and rigid examination, but it is no harder, no more rigid, than the importance of the subject demands. It is practically impossible for a person afflicted with color blindness to pass it. And in this lies its virtue. The "practical test" which Mr. Stone advocates is one that might possibly be passed by an unscrupulous person conscious of his inability to distinguish colors and shades. This is the weakness of the "practical test." Upon the ability of the motormen to distinguish promptly the signals set for their guidance depend the safety and the lives of the passengers.

Carbolic Acid Sale Stopped.—At the conclusion of the regular meeting of the Board of Health September 8, Commissioner Darlington announced that the following amendment had been made to the Sanitary Code: "No phenol, commonly known as carbolic acid, shall be sold at retail by any person in the City of New York, except on a prescription of physician, when in a stronger solution than 5 per cent." The action of the Board of Health in adopting an ordinance to check the sale of carbolic acid cannot be called timely. Such an ordinance should have been put in force years ago, when the ease with which would-be suicides could obtain the poison now proscribed was first pointed out in the newspapers. Tardiness of adoption, however, has not destroyed the wisdom in the law, and enforcement should be earnest and unremitting. Death by the carbolic acid method is painful beyond ready description. But this fact has usually made its appeal too late. Desperation has driven its victims to the cheapest and most available means of self-destruction, and it has come to pass that nearly half the suicides in New York City are accomplished by the deadly phenol. The carbolic acid route out of the world has particularly attracted women and girls. There is reason to believe this law will do more than drive the despairing to other means of self-killing. It will cause in many a case such delay in the execution of an ill-judged determination as will bring a sane and saving second thought to the fore.

Fixing the Blame.—Apropos of the epidemic of typhoid fever now raging in the Bronx most lay, and not a few medical, journals have found material for interesting though not always thoroughly understandable editorials. The old saw about an ill wind, etc., is doubtless true enough, but usually the wind is traveling at a hurricane rate in some quarter or other unchecked by physical laws that are ordinarily in operation. A typhoid epidemic may stimulate thought and engender the expression of more or less valuable opinion, but it is unfortunately a big price to pay for the senseless mouthings of those who are entirely ignorant of the circumstances attendant upon its origin and propagation. Probably no city approaching even one-half the size of New York, has a health board composed of men so well trained for their work or so conscientious in having that work carried out, and while the Board has not been openly condemned, disparaging remarks have been made. New York is a difficult city to manage because of its distinctly cosmopolitan type—education in matters sanitary must always be nearly a hopeless task when one has to deal with semi-barbarous illiterates from the mountains of Italy and other countries of the Old World, and no end of rules and regulations can rid them of filthy habits acquired through long years of groveling existence on their native soil. Some daily journals have even gone so far as to calculate the money cost of the scourge and have compared these figures with the astonishingly small cost of prophylaxis, assuming to know, of course, just how much in dollars and cents it really does cost to keep a colony of Italians *in statu quo*. It is a great mistake, to suppose that because we have fire companies there ought to be no fires, and because we have police patrol there ought to be no night brawls, and because we attempt to prevent disease no disease should exist. In spite of all precautions we are likely to have a severe outbreak of some disease or other at any time.

PHILADELPHIA.

Woman's Medical College.—This college is to have its own hospital for teaching purposes instead of using the Woman's Hospital which adjoins the institution. The separation has grown out of the refusal of the hospital to accept as one of its staff a youthful professor appointed last year by the college.

Texas Cattle Fever in Pennsylvania.—An outbreak of this fever has recently occurred among the cattle in the vicinity of Lancaster. The disease was brought from the south and spread by a car of cattle not labeled as coming from the infected district. State officials have the disease in check.

Home Study Hours Lessened.—The public school studies have undergone a revision lasting more than a year, and this is now complete with the exception of physiology which is soon to be added to the list. One of the main objects of the revision was to lessen the amount of home study required, this having become a serious complaint of the parents.

To Honor Dr. Chapin.—It is proposed to give Dr. John B. Chapin, Superintendent of the Pennsylvania Hospital for the Insane, Philadelphia, a dinner in October next, in honor of his half-century's work in behalf of the insane. Those desiring to participate in the function should correspond with Dr. Edward N. Brush, Superintendent of The Sheppard and Enoch Pratt Hospital, Towson, Md.

CHICAGO.

Opening of Swedish Hospital.—The new Washington Park Swedish Hospital, at Sixtieth Street and Vincennes Avenue, was recently dedicated, the dedicatory exercises being under the auspices of the Sophia Aid Society. Ten patients already are in the hospital. The building was completed August 25. The institution has accommodations for fifty patients. The founders believe the institution will grow rapidly. Dr. O. C. Young is the head physician. The staff is composed of Drs. John B. Murphy, Frank Billings, Archibald Church, William A. Evans and A. Hakanson. The operating room is equipped with all modern appliances.

Nervousness in School Children.—According to Dr. C. C. Krauskopf, assistant supervisor of the child study department of public schools of this city, it is estimated that one in every three of the school children is a victim of some form of nervousness. This is the finding of public school pedagogues after observations extending more than a year. The prevalence of nervous disorders among children is attributed to strenuous city life; impure city atmosphere; the bringing up of children in flat buildings; no relief from noise, day or night; lack of proper nutrition; late hours permitted by parents, and residence along cable and trolley car lines. The finding is based on statistics collected in every part of the city. Of the three hundred pupils examined by the child study department of the school board during the last year, a large majority of the defectives were found to be sufferers from nervous affections. The nervous affections usually took one of two forms: Sluggishness and mental depression, with tendencies toward melancholia, or uncontrollable nervous twitchings. In a great many of the cases nervousness is directly traceable to lack of proper food, accompanied by poor air to breathe, life in flat buildings, noise day and night, etc. It has become a recognized fact that everything possible must be done in the public schools to counteract the nervous effect of city life. A public school principal, who has made a careful investigation of the subject and intends to publish a monograph showing the effect of city life on the child, declared that parents have no conception of the appalling increase of nervous complaints among children.

Teachers in Good Physical Condition.—Of the 171 teachers examined by the child study department during the last vacation period, only six failed to pass the physical examination.

Donation for St. Luke's Hospital.—According to the will of the late Mrs. J. H. McVicker, $10,000 will be donated to this institution.

Mortality for the Week Ended September 3.—According to the Bulletin of the Health Department, for the week ended September 3, there were reported 491 deaths, 19 more than in the previous week, making an annual mortality rate of 13.27 per 1,000. Violence caused 69 deaths; acute intestinal diseases, 86; consumption, 61; and heart diseases, 32.

GENERAL.

Georgia Tuberculosis Commission.—Governor J. M. Terrell, of Georgia, has appointed a medical commission to investigate the extent of tuberculosis in Georgia and means of stamping out the disease. This is the first commission of the sort instituted in the South, and was created by an act of the General Assembly approved in August. The commission will cooperate with the State board of health and doubtless, also, with a committee on tuberculosis appointed some time ago by the State Medical Association. Dr. Charles Hicks, of Dublin, is chairman.

The Auto or the Horse—Is Either Safe?—Dr. F. W. Dalrymple, a prominent physician of New Rochelle, N. Y., was thrown from his buggy in a runaway accident and had his collarbone broken and head badly bruised.

Dr. Russel G. Andrew, Jr., a Coroner of Monmouth County, and a practising physician at Highlands, N. J., was seriously, if not fatally, injured on the same date, while returning from a visit to a patient at Sandy Hook. A private motor car, in which Dr. Andrew was riding at the rate of twenty-five miles an hour, jumped the rails opposite The Cedars on Sandy Hook. Dr. Andrew was thrown with terrific force to the ground. He was taken unconscious to his home an hour later, where his father, Dr. R. G. Andrew, Sr., a physician of Navesink, was summoned. Dr. Andrew found that his son had sustained a compound fracture of the right leg, was suffering from severe bruises on the head and hips, and probable internal injuries.

Chill Room Cure for Lockjaw.—A ten-year-old boy is battling for his life against a severe attack of tetanus in the big chill room of the Jetter brewery in South Omaha, Neb. When convulsions came on and the boy's condition grew worse the parents were prevailed upon to permit the boy to be taken to the chill room in the brewery. His condition improved immediately, but he objected to lying in the chill room and was taken back to his home. There the convulsions returned and the boy was taken back to the chill room. Within one hour after he was taken there the severity of the convulsions had been greatly reduced and the patient was able to straighten out his legs. Two days later the convulsions disappeared entirely and the boy was able to open his mouth and take nourishment. The physicians say that he will recover and that the new chill-room treatment will have saved his life.

The Cocaine Danger.—Not wholly a subject for cheerfulness are certain figures, just published in Brussels, which show an enormous increase in the output of coca leaves and in the manufacture therefrom of the alkaloid called cocaine. The raw material comes from Peru, and exports of it from that country have more than doubled since 1899. Last year they amounted to something like 1,300,000 pounds, the bulk of the product being gathered by Indians from the wild plants in the forests. Cocaine, of course, is of great usefulness in medicine, but it is being dangerously misused. Many makers of patent medicines are utilizing it on a large scale. It enters into the composition of numerous catarrh remedies, and is the active ingredient of a variety of nostrums which deaden pain by the simple process of reducing the sensibility of the nerves. The relief it gives in cases of irritation of the nasal passages is due to its property of contracting the smaller blood-vessels in the mucous membrane. People take these medicines without knowing that they contain cocaine, are relieved by them temporarily, and acquire a habit for the drug, which is quite as bad as morphine, being not less destructive to the nervous system. It is an excellent illustration of the fact that proprietary remedies which contain powerful toxic agents ought to be labeled with a suitable warning, under compulsion by the law. This is done in European countries, and any evasion of the regulation is punished with severe penalties.

When Vacation is Over.—In many of the cases where a family return home from their long summer outing apparently in the best of health, only to succumb to illness soon after, the family doctor lays all the blame on the water or sanitary conditions of the summer home, and sometimes quite unjustly, says a writer in *Harper's Bazaar*. Undoubtedly many country places are most unsanitary, but often it is the town house which is responsible for the low fevers and so-called "malaria" that attack us in the autumn. Where it is a possible thing no housewife should think of moving her family into winter quarters until the house has been aired at least a week. No water should be used from the taps (except for washing) until it has been allowed to run a couple of hours and the pipes are thoroughly cleared of the summer accumulations. It is also an excellent precaution to pour boiling water mixed with chloride of lime down each escape pipe and all toilet closets. The proportion of the mixture should be a heaping teaspoonful of lime to a quart of boiling water. The empty and long disused icebox or refrigerator should come in for a most thorough overhauling before

a particle of food is put into it. If the shelves are movable, as they should be, take them out and boil them thoroughly in the clothes boiler. Wash out all the inside of the box with as hot water as can be handled. Be especially careful to see that the little pipe at the bottom, which takes away the water from the melting ice, is absolutely clean and sweet. In our rather damp climate beds which have been unused for some time should be most carefully looked after, dried, and aired thoroughly before being again occupied. The cellar should come in for careful inspection, and be given all the air its small windows will allow. If it has a close, mouldy smell on being first opened a coat of whitewash will be found an excellent and inexpensive disinfectant.

Radium Rays and Diphtheria.—Considerable attention has been drawn to the therapeutic effects of radium and naturally much interest attaches to experiments in this field. The claim has been made that exposure for forty-eight hours to radium rays would prove fatal to typhoid-fever bacilli when placed close to the source of rays, while anthrax spores and lower organisms of various kinds have similarly been destroyed. Recently a series of careful experiments, made at the biological laboratories of the Massachusetts Institute of Technology, by Professor S. C. Prescott, seem to show that exposures of less than ninety minutes to radium rays have no destructive effect in the case of the intestinal bacillus (*Bacillus coli*) and the bacillus of diphtheria (*Bacillus diphtheriæ*), and also in the case of the bacteria of domesticated yeast (*Saccharomyces cerevisiæ*). The importance of these experiments is that they were performed with three varieties of bacteria essentially different, and the time conditions were such as would be encountered in using practically the radium rays as a germicide. Naturally the experiments with the diphtheria bacillus are of the greatest general interest, as it has been asserted that radium enclosed in a certain form of capsule and inserted in the throat of the patient would effectively destroy the organisms of the disease, and it has been suggested that for the cure of diphtheria radium might prove as effective as antitoxin. In these experiments no evidence was obtained which would indicate any possibility of the successful treating of diphtheria by destroying with the rays from radium the specific micro-organisms of the disease, and Dr. Prescott states as a conclusion that the use of radium tubes for this purpose cannot be recommended, nor can they be regarded as a substitute for antitoxin. Furthermore, he believes that where any benefits have been obtained from the therapeutic use of radium, the effect is not due to the destruction or weakening of the pathogenic bacteria, or disease-bearing micro-organisms, and that a further explanation must be sought. The subject continues to be of interest and an open question, as both positive and negative results have been obtained from the use of radium by physicians; but later reports do not seem to indicate any marked success or advances, while such experiments as those described above seem almost conclusive.

Tuberculosis Open-Air Treatment.—The new open-air treatment for consumptives, by which the patients remain night and day, awake or asleep, in a bath of pure atmosphere, is attracting much attention. Whether the weather is warm or cold, they are exposed as much as possible, being protected only from drafts. If it rains or snows they are not shut in, but are merely sheltered against the wet. Thus they have at all times a maximum supply of oxygen, which is hostile to germ life, while kept safe from further infection and supplied with plenty of nourishing food. The Federal medical authorities have become much interested in the enterprise, and Dr. George M. Sternberg, recently Surgeon-General of the Army, is urging the establishment of open-air hospitals on a considerable scale. Treatment will be restricted to those who are too poor to compass any means for their own relief, and whose removal from their ordinary surroundings will be to the interest of the community at large, in view of the infectiousness of the disease from which they suffer. The method adopted is to build a number of outdoor shelters, each one to accommodate only two patients, with an administrative headquarters for the physicians in charge. Of course, the plan as yet is in only an experimental stage, but if it proves as successful as is indicated by what has already been achieved, such open-air camps will doubtless be established on an extensive scale. Municipalities, for their own protection, can well afford to maintain them, the cost being by no means great. It is estimated, in the *Saturday Evening Post*, that nearly ten per cent. of all diseases that carry off human beings before, in the ordinary course of nature, they would die are caused by tuberculosis, which in this country destroys 160,000 lives annually. Nevertheless, it is entirely preventable by the adoption of a few simple measures of precaution. Consumption would largely disappear within twenty years if people would refrain from spitting in public or other places where their sputum may dry and be carried about in the air, together with any bacilli it happens to contain. By the adoption of sanitary measures the mortality from tuberculosis in France has been reduced within twenty years to forty per cent. In Germany it has been lowered in the same way by an equal percentage. Adequate statistics for this country are not obtainable, but in New York City since 1881 there has been a reduction of forty per cent. in deaths from consumption. The problem of getting rid of this frightful plague can be solved only by educating the people and by the rigid enforcement of regulations against promiscuous expectoration.

Ramsay's Latest Researches.—At the dinner of the chemists on September 8, Sir William Ramsay indulged in a prophetic remark which naturally arrests attention. He suggested the possibility that a discovery was imminent which would throw light on the origin of the "ordinary element." These may be, he intimated, "the products of the breaking down of radio-active elements of high atomic weight"—radium, uranium, thorium and one or two others. The hope to which he thus gave expression was doubtless based on recent but unfinished investigations, briefly described by him in a letter to *Nature* a few weeks ago. There is a general disposition now to explain the strange phenomena which characterize the behavior of radium—among them the evolution of a gas that slowly turns into helium—by assuming that some of the atoms of the first mentioned element disintegrate, and in so doing liberate stored energy. Sir William asked himself if it were not practicable to reverse the process and build up an element by a proper combination of material and energy. The latter would be required in a concentrated form, but a supply could apparently be secured by the breaking down of a radio-active substance. The task which is here outlined possesses great difficulties. Every working chemist knows how much easier it is to ascertain of what elements a compound is composed than to make them unite. Synthesis is very much harder to effect than analysis. Still, it has been possible in the laboratory to imitate nature's example in the production of indigo, camphor and

several other articles of commerce. In like manner the preliminary work already done by Sir William has encouraged him to think that perhaps one kind of atom can be transformed into another by a process of building up.

The Doctor's Income of the Future.—Doctors who believe—and apparently there are many of them—that the members of their profession are different from and superior to the members of all others, in that they are constantly endeavoring to put an end to the thing out of which they live, really ought to view their own mental condition with apprehension. The *Times* suggests that they "take something" for it before this queer delusion lets in a lot more and the unhappy victims pass beyond the possibility of help, even from such of their brethren as remain sane. Latest of many manifestations of the belief that the doctors, from a business point of view, are nobly cutting their own throats, is one that appears in the *Post-Graduate*. "It is not generally realized," says that high authority, "that the medical profession is the only one laboring conscientiously and faithfully to destroy its own source of income. Every improvement in hygiene and in sanitary science, every discovery of a specific source of disease, by improving the general health removes large amounts of money from the medical man's pocket and adds incalculably to the wealth of the community. The time will come when this fact will be generally realized." Possibly. But about the same time, there will be a realization, that the labor, conscientious and faithful as it is, and measurably successful as it has been, besides, is not destroying, or even tending to destroy, the source of the doctor's income. For the task imposed upon them is one that, if not quite endless, theoretically, most certainly will not be completed by this generation of doctors or by any generation of their successors in whom they can pretend to have a personal interest. One can conceive, of course, of a time when medical and surgical science shall have made such progress that everybody will live on indefinitely in a state of perfect health, and there will be nothing more for doctors to do, but an enormous "meanwhile" will precede that glorious age, and while it lasts the doctors are in no danger of starving.

International Congress of Dermatologists.—Upon the invitation of Dr. Hyde, of Chicago, Dr. Stelwagon, of Philadelphia, Dr. Fordyce, of New York, and Dr. Gilchrist, of Baltimore, the American delegates to the International Dermatological Congress, which was in session in Berlin during the present week, it was decided to hold the next Convention in New York. The venerable Professor James C. White, of Boston, was elected president of the forthcoming congress.

OBITUARY.

Dr. A. W. Butler, aged twenty-four years, died suddenly September 6, at the home of his parents in East Nashville, Tenn. Dr. Butler graduated in 1903 from the medical department of the University of Tennessee, taking high honors and winning an interneship at the City Hospital. Excessive application to work, both during student life and while in the hospital, contributed to his untimely death.

Dr. Edward P. Buffet, died at his home, 809 Bergen Avenue, Jersey City, N. J., September 10. He was born at Smithtown, Long Island, on November 7, 1833. He was graduated from Yale in 1854, and from the New York College of Surgeons in 1857. He had practised in Jersey City from that time.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

(Continued from Page 528.)

Section on State Medicine.

Control of Milk Supply.—A lengthy discussion on this subject was held. Dr. George Newman opened the conference. He said: A right understanding of the best methods of how most effectually to control and protect the milk supply depends upon a clear appreciation of the exact reasons and conditions which make control necessary. It is because the public, and perhaps even the profession, do not understand the latter as fully as they might that they do not appreciate the importance of the former or perceive the lines on which it should proceed. For convenience, the reasons necessitating control of milk may be broadly divided into two: First, there is the prevention of milk-borne disease; and secondly, there is the improvement and increase of the milk supply.

Typhoid Milk.—It was Dr. Michael Taylor of Penrith, who in this country first demonstrated the conveyance of typhoid fever by means of milk. This was in 1857. Since that date more than 160 epidemics of this disease have been traced to a polluted milk supply. Schuder states that 17 per cent. of all typhoid epidemics are due to the consumption of infected milk. The steps in the process of infection are briefly as follows: Enteric fever affects the intestine, and hence the excreta, especially in the early stages of the disease, are charged with large numbers of the casual bacilli. It is now known that the sweat, expectoration from the lungs, and the urine of a typhoid patient may also contain the typhoid bacillus. Indeed the urine in 25 per cent. of the cases generally contains large numbers of the bacillus (Horton Smith). There is also evidence to show that the bacilli may remain in the urine for long periods after convalescence, even for months and possibly for years. The bowel discharges and the urine are, therefore, the two chief channels by which the typhoid bacillus is excreted. It, therefore, readily gains access to the soil, to drains, and eventually on occasion to the water supply, and thus into milk and back again to man. The virus does not always pass in the discharges to water and milk, but may reach them by becoming dried dust. A small pollution may in this way set up widespread disease. The most common way for milk to become infected by the typhoid bacillus is through infected water (in 29 per cent. of milk-borne outbreaks according to Schuder). Another source of infection of the milk is when persons suffering from a mild attack of typhoid fever continue to work a dairy or otherwise deal with milk, and this has proved a frequent means of infection. Flies doubtless convey the germ of the disease not infrequently, as was shown in the Spanish-American war of 1898 and the Boer war of 1900-1. Though the typhoid bacillus appears not to have the power of rapid multiplication in milk it has the faculty of existing in milk for a considerable time (twenty days or longer) even when milk has curdled or soured, and may thus infect milk products, such as butter and cheese. But infection by milk products may be eliminated as of too rare occurrence to deserve attention. The bacillus does not coagulate milk like its ally the *Bacillus coli communis*

(which is a frequent inhabitant of milk). It flourishes in milk at room temperature and blood-heat, and does not produce acid or alter the appearance of the milk. The common channels of typhoid infection of milk, as illustrated in epidemics are as follows: (*a*) Personal contact with typhoid patients; (*b*) infection from washing milk vessels with infected water; (*c*) infection by the addition of infected water directly to milk; (*d*) infection from the air by dried typhoid excreta; (*e*) infection from contaminated cloths or clothes; (*f*) infection derived from water in which milk in vessels was being cooled.

Scarlet Fever and Milk.—The second infectious disease shown in this country to be transmissible by milk is scarlet fever. In 1867 Dr. Michael Taylor investigated such a scarlet fever ontbreak at Penrith. Since that date some seventy milk-borne epidemics of scarlet fever have been put on record. It is unnecessary here to do more than mention two broad series of facts which should not be forgotten in investigating milk-borne scarlet fever outbreaks, or in endeavoring to prevent them. First, while in similarly-conveyed outbreaks of typhoid fever it is necessary to consider the various ways in which human infection has been conveyed to milk, in scarlet fever it is necessary to consider in addition the possibility of cow infection. Human infection in scarlet fever outbreaks is almost always conveyed by direct cnotact, and not, as in typhoid, through the medium of water or materials. Since 1881 there has been necessary the added inquiry as to the communicability of zymotic disease from the cow. The case of cow infection of scarlet fever is not yet proved or established. But there is certainly not a little evidence to show that previously to some scarlet fever outbreaks, and outbreaks of aberrant forms of disease to be mentioned immediately, certain pathological conditions of the cow's udder have been found to be present: and it may be that further research will prove that there is causal relation between such conditions of the cow and disease in persons consuming the milk derived from such cows. Certainly there is sufficient evidence to make necessary careful axamination of the cow in all milk-borne outbreaks of disease. The second point to which attention must be called is the clinical modification of scarlet fever which has been milk-borne. Such disease is generally mild, and accompanied by a large number of ordinary sore throats. Even in the scarlatinal cases the disease has a tendency to remain localized to the throat. The rash is evanescent, and the desquamation scanty. There is commonly a marked absence of post-scarlatinal nephritis, and a marked presence of alimentary disturbances, sometimes amounting to intoxication.

Diphtheria and Milk.—In 1878 evidence was first forthcoming in support of the view that diphtheria might on occasion be spread by milk. In that year Mr. W. H. Power made an inquiry into the outbreak of diphtheria in North London, and although it was clearly shown that milk was the channel of infection it was not discovered how the milk became infected. By a process of exclusion Mr. Power suggested that there may have been risk of specific fouling of milk by particular cows suffering, whether recognized or not, from specific disease. Subsequently to the discovery of the Klebs-Löffler bacillus, Klein investigated the question of cow diphtheria, and Dean and Todd have recently thrown further light on the subject. There can be little doubt that milk is a favorable medium for the *Bacillus diphtheriæ*. The organism both lives and multiplies in ordinary sterilized milk, but it thrives better in milk at comparatively lower temperatures than 37° C. In ordinary milk, unsterilized and unprepared, the commoner organisms multiply much more rapidly, and so the diphtheria bacillus is in all probability soon crowded out. The cases, however, in which the *Bacillus diphtheriæ* has been actually isolated from milk are extremely few. He further spoke of sore throat and epidemic diarrhea both as being conveyed by milk and presented a lengthy argument concerning the conveyance of tuberculosis by this medium. Improvement of the milk supply, the conditions of the milk trade, and the quality of milk were other topics taken up by Dr. Newman. He very generously accorded to this country a just commendation for the excellent work done on the milk supplies of our large cities and seemed to think that England was behind in her study of the problems of pure milk supplies.

Hygiene in Elementary Schools.—Dr. W. N. Barlow spoke of the needs of teaching simple hygienic subjects in the elementary schools. Nearly every medical officer of health, he said, in his annual report, deplores year by year the immense wastage of infant life, and comments upon the causes contributing thereto. It has been pointed out that, while some amount is due to neglect and indifference, very much more is due to ignorance. Hundreds of lives are lost yearly through ignorance of how to feed children. Hundreds of lives are lost yearly through ignorance of the simple laws of health. A man with a prize dog will take immense pains to learn how to feed the animal and keep it in health, but will take no pains to see that his baby is properly fed and clothed, or how to keep himself healthy. Many hundreds of infants' lives are lost by reason of clinging to old superstitions regarding measles and whooping-cough. They are still considered mild diseases and of no account, in spite of oft-repeated warning that they kill more than all the other what are called "dangerous infective diseases" put together. It is a common superstition in Liverpool, that if a child with whooping-cough be taken across the river when the tide is on the ebb, that the disease will ebb with it, the result often being that an attack of bronchitis follows and the child's life ebbs altogether. Efforts have been made to lift this pall of ignorance by scattering leaflets broadcast dealing with infant feeding, etc., and by popular lectures; but the fact remains that, among the poorer classes, most mothers cannot be taught; some will not be taught; and it has now come to be accepted that the best way to fight the battle is to do what is possible by means of leaflets and lectures with the present generation, and to improve the next generation by teaching a few of the elementary facts regarding personal hygiene, domestic hygiene, and the feeding of infants to the children (especially the girl children) now at school. Now many education authorities, while looking more or less favorably upon the suggestion that hygiene should be taught in public elementary schools, say, "But how can we include this subject? our curriculum is already full to overflowing, and there are already many subjects much more valuable which ought to be taught and for which there is no room." Others say, "We already teach it in the subject called domestic economy." With regard to objection No. 1, I cannot do better than take a few extracts from Herbert Spencer's Essay on Education, a most valuable book, which I would recommend to all who have not yet read it.

Spencer deplores that the useful in education is sacrificed to the ornate, especially with respect to women. He says: "In the treatment of both mind and body, the decorative element has continued to predominate in a greater degree among women than men. In their education the immense preponderance of 'Accomplishments' proves how use is subordinated to display. When we have named reading; writing; spelling; grammar; arithmetic; and sewing, we have named all the things a girl is taught with a view to their actual uses in life." Again he says: "If there requires further evidence of the rude, undeveloped character of our education, we have it in the fact that the comparative worths of different kinds of knowledge have been as yet scarcely even discussed—much less discussed in a methodic way with definite results. Not only is it that no standard of relative values has yet been agreed upon, but the existence of any such standard has not been conceived in a clear manner." Again, "For complete living it is necessary not only that sudden annihilation of life shall be warded off, but also that there shall he escaped the incapacities and the slow annihilations which unwise habits entail. As without health and energy the parental, the social, and all activities become more or less impossible, it is clear that this secondary kind of direct self-preservation is only less important than the primary kind: and that the knowledge tending to secure it should rank very high. Consider how ill-health hinders the discharge of duties, makes business often impossible and always more difficult, and produces an irritability fatal to the right management of children." "Vigorous health and its accompanying high spirits are larger elements of happiness than any other things whatever, the teaching how to maintain them is a teaching that yields in moment to no other whatever!" One last quotation: "Is it not an astounding fact, that though on the treatment of offspring depends their lives or deaths, and their moral welfare or ruin, yet not one word of instruction on the treatment of offspring is ever given to those who will by and by be parents. Is it not monstrous that the fate of a new generation should be left to the unreasoning custom, impulse, fancy, joined with the suggestions of ignorant nurses, and the prejudiced counsel of grandmothers? To tens of thousands who are killed, add hundreds of thousands who survive with feeble constitutions, and millions who grow up not so strong as they should be, and you will have some idea of the curse inflicted on the offspring by parents ignorant of the laws of life." In the face of words like these from such a man as Herbert Spencer, can it now be advanced that there is no room in the preliminary schools for instruction on hygiene.

School Diphtheria in London.—Dr. C. J. Thomas gave a paper on this subject. His conclusions were as follows: 1. Diphtheria is spread by schools to a certain and considerable degree. 2. It is spread by direct personal transmission. 3. It can be checked by swabbing and excluding children carrying diphtheria organisms. 4. These children are chiefly mild, actually suffering cases. 5. Their age is usually between five and eight years. 6. Pseudo-diphtheria organisms may safely be ignored. 7. School closure for diphtheria should be looked upon as a confession of impotence and defeat. 8. There is urgent need of greater recognition even on the part of medical practitioners of the rôle of slight cases and carriers. In many instances children sent home by the teachers have returned after seeing a doctor who has said they were not suffering from diphtheria, although their throats swarmed with diphtheria organisms. 9. All contacts with diphtheria cases should be rigorously swabbed before being allowed to mix with the general population. Disinfection of homes without this precaution is futile. 10. Much greater facilities for bacteriological examination need to be provided. 11. Could not the annual report of medical officers of health dealing with such facts as these become a means of education on these points? At least could they not be distributed to each member of the profession in the sanitary district?

Poverty and Public Health.—Dr. T. P. Whittaker spoke of the influences of alcoholic beverages and this general subject. His paper contained many interesting statistical summaries, but no large or new generalizations.

Pauperization.—Mrs. B. Bosanquet gave an interesting paper on this subject. Among other things she said that physical conditions which characterize the kind of life deplored are, generally speaking, dirt, overcrowding, insanitary houses, foul air, and insufficient or inappropriate food and clothing; to these must be added the presence or results of disease in the physical organism itself. All will agree that there is no single remedy for these various evils; each calls for its particular remedy, in devising which the whole skill of the expert is required. But it is not these particular remedies which are considered here; it is the general method of their application. The medical and sanitary experts will tell the particular remedies for drink, disease, and physical backwardness; the point to consider is how these remedies may be most effectually and universally applied. In short, the importance of a definite policy of reform should be urged. For in opening up an attack upon these evils there are two quite distinct policies between which have to be chosen. There is first the policy which assumes that one and all of these very dissimilar results are due to the same cause—namely, poverty; and which, therefore, aims at merely supplying from outside what is more obviously lacking. It assumes that the recipients are desirous and capable of living the healthier life, and are debarred from doing so by their poverty alone. This is the policy which thinks the way to reform lies through free meals and clothing, municipal housing, and other subsidies from charity or Poor-law institutions. The other policy is adopted by those who have found that these evils frequently exist where there is no poverty to account for them, and are driven, therefore, to probe more deeply for the real causes. These they find in the absence of those dispositions, faculties, and interests, which we are apt to sum up in the word "character;" and they find, moreover, that poverty itself is frequently but one among many outcomes of this lack of character. Hence they maintain that the true method of attack is to strike straight at the root of the evil, and by education and the healthy stimulation of interests, to arouse the energies and knowledge which will lead the backward into the ranks of the forward. A few typical cases may illustrate how important this question is of choosing a right way of applying remedies. Sanitary experts tell that one great cause of ill-health and vice is overcrowding and insanitation. Desiring to apply this knowledge rapidly and effectively, some authority clears an insanitary area and puts up dwellings of the most approved type. One of two things happens; either they permit the old inhabitants to take possession

of the new dwellings, in which case they are soon reduced to dirt and squalor; or—and this is what generally happens in London—the authority declines any but respectable tenants, and the old inhabitants go off to make a new slum elsewhere.

Or take an instance quoted by the chairman of the Birmingham Housing Committee in last week's *Spectator*. An owner was called upon by the Housing Committee to spend a large sum of money on two courts. He did everything that was required, yet now, six or twelve months afterwards, the tenants have made the houses almost as dirty as ever, and this is in no way due to the way in which the repairs were done." Take another instance. The children in an elementary school being badly nourished, the remedy naturally suggested is good food, and the reform-institutes meals at school. The inevitable result is that many mothers, relying upon these meals at school, reduce the number of meals at home, and the evil, instead of being reduced, is spread over an increasingly wider area. Or another: the doctors tell us that the great cause of infant mortality is insufficient or impure milk. Sterilized milk in bottles is supplied, until two difficulties are confronted—on the one hand that mothers may be tempted by it to cease to nurse their own children; on the other hand that, owing to the inevitable association between bottles and medicine, will only give it to their children so long as they are definitely ill. It really seems sometimes as if all efforts were useless. And yet the fault lies in no sense in the remedies themselves; it is the application of them which is wrong.

It is absolutely necessary that before any progress at all can be made the people themselves should be enlisted on our side, and to do this their minds must be influenced, we must get them to take an active intelligent interest. It is a far more difficult task than one of handling bricks and mortar, and food and clothing; but it is essential. If we can make them care for clean houses we can give them clean houses to live in; if we can make them take an intelligent interest in their children they will not fail to feed them: and if we can teach them something of the relation of food to the needs of growing children, they will feed them properly. It may be asked what proof I can offer that it is mainly ignorance and lack of interest which are at fault, and not poverty alone. I appeal for support mainly to the experience of intelligent workers amongst the poor, who have learned slowly but surely how uncertain the connection is between good earning and a good home. For those who find a greater security in figures I may refer to the rough test afforded by Mr. Rowntree's investigations in York. You will remember that of his 27 per cent. living in conditions of apparent poverty over 17 per cent. were in receipt of incomes which should have raised them out of it, while less than 10 per cent. had incomes insufficient for a healthy life. Even on this rough test, therefore, the great majority might have led healthy lives if they had known how and cared to. But more than this, we who have seen much of the lives of the poor know how often in cases of exceedingly small income, of real poverty, the worst forms of evil are absent. That is, the homes are clean, the children are healthy and well cared for, and the family life sober and industrious. Now, you will grant me that in those numerous cases where people live unhealthy lives through sheer ignorance or self-indulgence the only remedy is education and stimulus. To give money in such cases is simply to subsidize the public house and gambling; to give food is to set free more money for the same purpose; to feed the children at school is to check the supply of meals at home; while no one has been ingenious enough to even suggest a gift which will make lazy people clean.

It is not so immediately obvious that this policy of subsidising is useless in cases of real poverty, but it is just as certain, except under very definite conditions and in very definite cases of misfortune.

Consider with me for a moment what are the conditions which make men efficient workers, capable and strenuous. Some of us, no doubt, work from ambition and the desire to rise to the head of our profession; others from sheer love of our work. But for the vast majority of men the chief motive is the sense of responsibility for their own lives and those of their family. To all of us in some degree, to most of us in a very great degree, work is repugnant, and strenuousness is difficult; it is much easier to let ourselves go, to work little rather than much, to be slack rather than efficient. Against this natural indolence there is no spur so effective as a man's interest in the home and wife and children for whom he has made himself responsible. Here and there are men with wider interests, who do not need this spur; but this is, or may be the common birthright of all mankind, and deprived of it the majority lack either courage or strength to live strenuously. To realize what a man becomes who has cut himself adrift from these natural interests without substituting others as potent, we need only turn to the forlorn tramps and vagrants who drag out their listless lives in wandering between casual ward and common lodging-house.

It is for this reason that any movement which tends to lessen a man's responsibility for his own family life does far more to increase than to lessen poverty. It may be urged that you are only helping a man to fulfil his responsibilities, that you have no intention of undertaking them altogether; and between individuals, between friends and neighbors, this is a possible though difficult position. It is next to impossible when the movement becomes a general one, and some charitable or State institution intervenes to share the work of providing for the daily needs of the family. The people who are ready to impose upon the benevolence of a neighbor are comparatively few, but still fewer are the people who are at all reluctant to get all they possibly can from an impersonal source of charity or relief.

(To be Continued.)

WILL'S HOSPITAL OPHTHALMIC SOCIETY.

Stated Meeting, held April 11, 1904.

The President, Charles A. Oliver, M.D., in the Chair.

Diseases of Conjunctiva.—Dr. Harold S. Goldberg opened the discussion on this subject, demonstrating the conditions seen in an exhibit of macroscopical and microscopical specimens, illustrating the gross and minute changes found in various conjunctival diseases. He showed the microscopical appearances of the invaded structures in diphtheric conjunctivitis (the germ of diphtheria being, he said, quite a frequent successful invader in the conjunctival soil), and differentiated them from those which are seen after gonorrheal conjunctivitis. He believed that the streptococcus is, as a rule, responsible for the gross changes seen in the diphtheritic types of conjunctival disease. He showed the relative effects of benign and malignant tumors

upon the membrane, contrasting these in their differences. He exhibited the behavior of various granulomata, and gave a résumé of the condition of the conjunctival structure in a case of perforating panophthalmitis as one of the results of endogenous infection from typhoid bacilli. He said that there was little known of the difference in the histology between diphtheritic and pseudomembranous conjunctivitis; the Klebs-Loffler and xerosis bacilli being so much alike morphologically as to make their differentiation difficult. He dealt at some length as to the relative actions of the various antitoxins. He spoke of the epidemics of conjunctival disease to which the hospital had been subjected, and cited the different modes of treatment by which the condition had been successfully combatted. He had found that the recent epidemics of conjunctival diseases in this city (Philadelphia), could be traced to the diplococcus lanceolatus. He compared these findings with those which he had read of as having been seen in other cities and countries.

From a large experience Dr. Frank Fisher had found that by a constant repetition of similar cases he had been enabled to differentiate clinical signs which he had learned to treat and manage by definite and well gauged rules: One of these had been the free use of saturated solutions of chlorate of potassium in diphtheritic and so-called pseudomembranous conjunctivitis. He had found that if this drug is used in such cases there is less danger of corneal involvement, and that there are fewer cicatrices left in the conjunctival membrane. In association with the drug, in combination with warm applications and the use of mild detergents locally, he made free internal use of the tincture of the chloride of iron. He stated that he had found that the application of nascent silver salts was not of any benefit in cases of diphtheric conjunctivitis. He had noticed that the cicatrices following diphtheria of the conjunctiva resembled a condition of cirrhosis. He classified pseudomembranous conjunctivitis and diphtheric conjunctivitis together. He always treated diphtheria of the conjunctiva systematically as well as locally. He believed trachoma to be nothing more than the excessive stages of ordinary follicular conjunctivitis; trachoma being a second or tertiary stage of true granular conjunctivitis—a condition in itself in which there is more or less atrophy of the follicles. In these cases, there are, he believed, all of the sequelæ of repeated inflammation, such as contraction and distortion of the lid, nebular pannus, and dry, hardened or greasy remains of the conjunctival membrane. In true trachoma, he took care to express all of the follicles in the conjunctival sulcus, preferably by the finger nails, following this procedure by the use of tannin, boroglyceride, and silver. He believed that dilation of the lacrimal canals and ducts was useful in offering better drainage for the vitiated secretions. Empirically, he had become favorably impressed with the results that he had obtained by the judicious use of alum in the late stages of gonorrhœal conjunctivitis. He also usefully employed solutions of acetate of zinc, chloride of zinc, biborate of soda, and boracic acid. Adrenalin he had used, but did not find its employment of any advantage.

Dr. S. Lewis Ziegler's experience in acute conjunctivitis had been that the more simple and the less irritating the application had been, the more quickly good results were obtained. As a rule, he employed four of five grain strength solutions of silver nitrate for the first application only, followed by such drugs as glycerole of tannin, boroglyceride and argyrol. These should be used ad seriatim, as all local applications sooner or later lose their effects and must be changed. He had found the best results from the employment of biborate of soda and boric acid in simple solutions. If the muco-pus persists alum, one to four grains to the ounce, will be most efficient. (The acetate of zinc is of value when the convalescence is slow). In the chronic forms of the disease, such as trachoma, he had had useful recourse to rapid dilation of the lacrymal passages, together with intranasal applications. In the purulent forms of conjunctivitis he made a daily application of a ten grain silver nitrate solution, neutralized by salt, and washed off with boric solution. Argyrol he also employs or else gives to the patient to be used at home. Mercuric bichloride (two grains to the pint) he used for irrigation in the early stages (and later, one grain to the pint), with the large bulb dropper, every fifteen minutes to a half hour day and night until acute stage is past. He applied ice pads constantly.

Dr. P. N. K. Schwenk said that his experience had been that all cases must be treated empirically. In simple ones he used weak solutions of nitrate of silver, boracic acid, and biborate of soda. Believing in the identity of granular conjunctivitis and trachoma (they differing alone in points of rapidity of development and severity of symptoms), he resorted to similar treatment modified to suit the existent conditions. Empirically, he had found the use of boroglyceride of great value in the treatment of diphtheric conjunctivitis.

Dr. Charles A. Oliver stated that the majority of cases of conjunctival disease were microbic in type, the clinical signs being in definite relationship with the anomalies of reaction to the preponderant acting germ. He considered that every ordinary conjunctiva, no matter how well cared for hygienically, was a harboring place for germ life—of both useful and harmful types: in fact, he considered that the membrane was, by this reason, kept in better condition, and made better able to withstand the attacks of injurious forms and coarse degrees of injurious bacterial colonization. He explained the difference between the scavenger type of germs and the serum consuming varieties. He showed how the anatomical relationships and peculiarities of structural formation rendered it more difficult for certain forms of bacterial growth (for example, the difference between related bacilli and cocci) to gain access to favorable resting grounds. He subdivided conjunctival disease in strict accordance with the clinical manifestations of the prevalent germs, and was thus able, by repeated bacteriological study during the course of the disease, to so regulate his therapy as to give the quickest and the best possible results in any given case. He had ceased to be disturbed as to prognosis in cases in which formerly he had had the gravest doubts as to useful recovery. Cleanliness of the parts, hibernation of germ life, destruction of the floral cells, with the least disturbance to the invaded faunal cell as possible, with protection to the most important contagious tissues, constituted his bases for therapy. He emphasized the relationship of the state of the patient's general health to the conjunctival condition at hand, this being particularly true in gross forms of disease, for example in Klebs-Löffler bacillus conjunctivitis in which he had obtained the most brilliant results by the early use of subconjunctival injections of antidiphtheritic serum; and in the scavenger type as a part of multiple infections of the mucous tract, in which general mucous therapy was a necessity. In his bacteriological studies he had come to the conclusion that all conjunctival diseases are primarily the results of mixed infection; one or more types of germ life gaining the ascendency, and giving the clinical peculiarities to the individual case. In the destruction of the parts, he

had found that it was not the prevalent microbe which destroyed the organ, but that the particular microbic invasion so reduced the protective agents in their activities as to allow them to become the prey of the pyogenic forms of bacteria. He stated that it should not be forgotten how certain types of germ being in an involutional state from their ancestral forms having become exhausted in different mucous soils (those in the urethral canal, for example, giving rise to a chronic and hardly noticeable gleet) are placed in a new pabulum-field (in a fresh soil such as the conjunctiva) would soon have their successors become optimal in condition and virulent in action (coarse gonococcal conjunctivitis). Conversely, from experiments and studies that he had made, he had found that gross forms of gonococci flourishing in a good soil would when placed in previously used and hence practically barren soils, soon become involutional in condition, oftimes monstrous in form and negative in action. He described the term "granular conjunctivitis," believing the conjunctival inflammation as merely secondary to reaction in the underlying microbic nestings of vegetable life with destruction of the adjacent faunal cells; resulting in cicatricial contraction and loss of the involved parts. He showed why the conjunctiva of the infant is less liable to injury from gonococci than that of the adult—giving a series of illustrative cases for explanation. He cited several examples occuring in the eye wards of the Philadelphia and Presbyterian Hospitals which well illustrated these differences.

Dr. L. E. Marter spoke of the injurious effects of chlorate of potash, if used in too great amounts. He gave a most interesting account of his experiences with the employment of varying strengths of solutions of permanganate of potassium in the different types of conjunctivitis, and inquired if the experience of the other members had been similar to his.

Dr. Samuel H. Brown stated that he wished to place upon record the almost constant plan of successful treatment of chronic cases of trachoma in the clinic of Dr. Conrad Berens, his chief—*i.e.*, by the use of fifty per cent strengths of boroglyceride. Incidentally, he had seen most favorable results in such cases from the local employment of graduated dosages of adrenalin—he having found this drug a most excellent adjuvant.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Regular Monthly Meeting held Monday, April 25, 1904.

The President, Wendell C. Phillips, M.D., in the Chair.

The scientific business of the evening consisted of a series of papers on the bacteriology and source of various food products and of the water supply of New York City.

Typhoid Fever and Oysters.—The first paper of the evening was by Dr. Cyrus W. Field, assistant bacteriologist of the Department of Health of New York City, who described some bacteriological observations relating to the transmission of typhoid fever by means of infected oysters. Oysters were infected with typhoid fever bacilli and then observations at regular intervals made with regard to the number of bacteria to be found in them. It was found that in healthy oysters the number of bacteria becomes gradually reduced so that on the second day there are only about half as many as on the first day, while on the ninth day practically all the bacteria are dead and failed to give colonies when plated for counting purposes.

Typhoid Bacilli and Salt Water.—During the experiments the oysters were kept in ordinary sea water and it was resolved to study the effect of this upon typhoid bacteria. It was found that if sea water became infected with typhoid bacilli, the number of the microorganisms became gradually reduced almost in the same proportions as had been noted in the observations made upon oysters. Where at first after contamination 200,000 bacteria were found to the cubic centimeter, after twenty-four hours only about 100,000 bacteria were to be found in the same space, and on the ninth or tenth day the bacilli had entirely disappeared. When the oysters were kept in contact with the same water conditions were not so favorable for the disappearance of bacilli as would usually happen with the ebb and flow of tidal salt water. Accordingly observations were made, changing the water every day and then it was found that after four days no bacilli could be found. The salt water itself seemed to act as a disinfectant under favorable conditions. These observations are in accord with those of Foote, made at New Haven in 1895, where he found that typhoid bacilli were destroyed at the end of ten days. If the water, however, in which the oysters were kept was cold, then the bacilli remained alive for from four to six weeks. In a word, cold inhibits the antiseptic action of salt water.

Dead and Dying Oysters.—Dr. Field made a series of observations also with regard to dead and dying shellfish, that is, clams as well as oysters. In these cases it was found that the lack of vitality in the animals served to make them an excellent culture medium for bacilli. Where, for instance, the original contamination showed from ten to twenty thousand bacteria to the cubic centimeter, this number soon ran up even to 100,000 whenever the oysters or other shellfish were dead, or even when they were not in normal good health. As the opposite happens, as a constant reduction of the number of bacteria is found when the shellfish are healthy, the importance of this factor in the transmission of typhoid fever must also be taken into account. During the course of shipment it is not unusual for a certain number of oysters to suffer so severely as to possess no vital reaction. If by any chance these were infected before the journey began, if they should be placed under water in the neighborhood of other oysters at the end of the journey, they would almost certain serve as a source of infection for oysters near them.

The Oyster in Typhoid Fever.—Dr. Walter Bensel, acting sanitary superintendent of the Department of Health of New York City, discussed the oyster as a possible agent in the transmission of typhoid fever in and around New York City. He said that typhoid fever occurred in New York City only in sporadic cases and evidently, therefore, not as the result of transmission through the water supply. Careful investigation showed that a considerable proportion of people who have been constantly in New York City for a month before coming down with typhoid fever were habitual drinkers of raw milk, or frequent eaters of raw oysters. There remained, however, a certain number of cases in which neither of these causes could be considered as active, but in which raw vegetables, or other sources of infection, must be looked for. Besides, as the inquiries had to be made usually several weeks after the actual infection took place, patients frequently had forgotten with regard to important details, or were too ill to give the information and, as could well be understood, friends could not supply it satisfactorily.

Oyster Beds and Contagious Material.—An investigation of the source of oysters eaten in New York City had been undertaken by the Board of Health and

this served to show very well that there was every reason to suspect oysters as not only a possible, but a frequent source of infection. Dr. Bensel then showed by means of photographs the condition of affairs that exist on the Long Island coast of Long Island Sound, on the Connecticut coast of the Sound, on Staten Island and along the shores of the various "kills" in New Jersey from which oysters are collected and in the creeks of which oysters are stored for a time and go through the process known as fattening for the market. This process is always carried on in brackish water, usually at some distance from the actual oyster beds and consists in the irritating effect which more or less fresh water has upon oysters, causing them to absorb water and look fat and plump. Many of these creeks cannot fail to be contaminated by sewage from the banks, and as a matter of fact no special precautions are taken to avoid this.

Sewage Material and Oyster Fattening.—In many places on Long Island oysters are fattened on the lower floor of oyster houses along the banks of the stream, the level of this floor being slightly below that of the water, especially at high tide. It is not an unusual thing to find privies, barnyards, poultry yards and other such extremely undesirable sources of the worst kind of sewage material within a few yards, sometimes within a few feet, of the banks of the stream on which the oyster houses are built. There is not even the more or less questionable advantage of water flowing outward constantly, which might serve to carry off sewage material. There is a certain amount of influence of the tides in these creeks and this often delays the onward flow of water for hours at a time, thus allowing sewage material to become generally diffused in the water which is to serve for the purpose of fattening the oysters.

Oyster Barges and Sewage.—Along the Connecticut coast and in various parts of New Jersey oyster barges which permit a rather free inflow and outflow of water are used for the storage and fattening of oysters after they have been taken by means of the dredge. The Connecticut coast is in certain places where oysters are most plentiful and where the trade is briskest, rather thickly inhabited. Towns containing from twenty to fifty thousand inhabitants empty their sewage into streams which are used for fattening the oysters. In New Jersey not infrequently along the creeks in which oyster barges are anchored privies and outhouses are situated, the droppings from which are expected to be carried off immediately into the water. In one striking picture the outhouse for a factory was situated directly over the water within twenty feet of an oyster barge.

Railroad and House Drainage.—Some of the photographs exhibited showed the pouring of house drainage of various kinds from wooden troughs into the creeks in which the oyster floats were and it was very evident that the washings from the streets of many of the little towns are carried directly into the stream every time that there is more than an ordinary rainstorm. In some of the towns in New Jersey the sewers empty directly into some of the rivers in which oysters are stored often for weeks before being sent to market. Through these sewers factory drainage of various kinds finds its way to pollute and discolor the flowing water. At one point a number of oyster floats were anchored not very far from a railroad bridge across which are carried many trains every day. It is easy to understand that under such circumstances it will not infrequently happen that fecal and other excrementitious material will find its way directly into the water from the cars.

New York City Milk Supply.—Dr. William Hallock Park, the assistant director of the Research Laboratory of the Department of Health of New York City, described the sources of New York City's milk supply and discussed the method by which the Board of Health endeavored to improve the quality of this important food material. A city inspector by the privilege of the State Commission of Health is allowed to visit various parts of the State, wherever there is a report of possible contamination or of conditions likely to make the milk supply unhealthy. The milk supply of the City of New York, however, comes from distances on a radius of three hundred miles from the States of Pennsylvania, New Jersey, Massachusetts, besides New York itself. Milk comes from as far North as the St. Lawrence. Owing to the absence of funds for this purpose, inspection falls short of what it should be.

Inspection Work.—Wherever there is absolute neglect, farmers are warned and notices are sent to them giving general directions how dairies must be cared for, cattle housed, milking carried on and milk preserved. Special emphasis is laid on the necessity for immediate cooling of the milk, because it is well known that at low temperatures bacteria will not grow in milk, while at ordinary temperatures they grow luxuriantly. It is not so much the bacteria which get into the milk, especially if there is any sense of cleanliness at all, but the rapid multiplication of them that causes the danger with regard to milk. One method of enforcing this precaution is to insist with the railroad company that milk to be delivered in New York must be brought into the city at a temperature of fifty degrees. Not infrequently it happens that the railroad journey is not long enough to permit the milk to reach so low a temperature unless it is already cooled when it reaches the railroad companies. Accordingly the railroad companies insist on the farmer having his milk cool when delivered on board of the cars.

Insidious Dangers of Milk Contamination.—Dr. Park gave some examples of the insidiousness of the danger of infection from milk under circumstances where it may be least expected and may seem unaccountable. A series of cases of scarlet fever occurred in several schools, all of them supplied with milk from one source. The milk was supposed to come from an excellent farm on which all the sanitary precautions necessary for the delivery of good milk were maintained. It was found on investigation, however, that the demand for the milk of this farm had been so heavy that they had been unable to supply it entirely and had made up the deficiency in their own product by securing milk from a farm some distance away. The conditions on this second farm were as unsanitary as can possibly be imagined. In the barn in which the cows were kept there were no windows, the ventilation was very poor and dirt was everywhere. As a matter of fact, a septic condition was found to exist in one of the cows and some of this material had evidently found its way into the milk and was the source of typhoid fever.

Typhoid Fever and Milk.—Dr. Park also gave some examples of how easy it is for typhoid fever to contaminate the milk supply on farms where the well and the privy are not far from one another and where a certain amount of leakage is almost sure to take place. In this case the vessels in which the milk was stored are washed with the water and thus readily become contaminated and the milk stored in them becomes a veritable culture medium at times of an almost pure culture of typhoid bacilli.

Work of Milk Commission.—Dr. Park considers that these facts show the necessity for the existence of the milk commission which was organized and is maintained

because neither the State nor the city had sufficient money at command to secure proper inspection of the milk supply. Unfortunately there is not the response to the commission's effort on the part of doctors that should in all reason be expected from them. There is a complaint that certified milk is too dear and so it is not used except by the wealthier classes. On the other hand, inspected milk, though only slightly costlier than the ordinary unexamined milk, is utterly neglected. Even hospitals prefer to get ordinary milk in bulk, though they would have to pay only about one-third a cent a quart more to secure inspected milk. By inspected milk is meant that it is the product of farms and dairies in which the farmer takes all the ordinary sanitary precautions in order to prevent, as far as possible, the occurrence of all bacterial contamination and in which particularly, immediately after milking, the milk is made cold so as to prevent it from becoming a culture medium for the growth of micro-organisms. Undoubtedly the recommendation of this milk would encourage other farmers to take the precautions necessay and thus bring about a gradual improvement of the city's milk supply by the education of the farmer.

Water Supply and Typhoid Fever.—Mr. Henry E. Bramley, Chief Sanitary Inspector of the Department of Health in New York City, discussed the city water supply with particular reference to possible contamination with typhoid fever bacilli. The first part of his paper consisted of a historical review of New York's efforts to obtain pure water. The first reservoir, planned in 1774, was to cost £2,500 and was situated on what is now East Broadway, about Pearl Street. Later the Manhattan Water Supply Company was organized, which obtained its water from wells for distribution to the citizens. Of late years, of course, the main source of New York's water supply has been the Croton region, and there is no doubt that greater care and more frequent inspection is needed than has been the rule so far. The Board of Health are accomplishing much for the protection of the city, as may be understood from the fact that 18,000 cesspools were cleaned during the last year in order to prevent possible infection.

Legal Aspects of Watershed Control.—Harford P. Walker, Esq., assistant Corporation Counsel, of New York City, one of whose main duties is in connection with the water department of the city, discussed the legal aspects of New York City's control of its own watershed. He said the ideal state of affairs for the city would be for it to own several hundred feet of ground alongside the creeks and streams and lakes from which it drew its water supply. Already $7,000,000 have been spent in thus protecting the city water from possible contamination. It will cost $5,000,000 more to secure the rest. In the meantime care must be exercised and the assistance of the Board of Health asked in co-operation with the water department in preventing nuisances from proving sources of infection. Unfortunately the present state of the law with regard to contamination of public water supplies in New York State is not satisfactory for protective purposes.

Webster Act.—As the result of the cholera scare, something over ten years ago, the Webster act was passed by the legislature of New York and signed by the Governor, giving New York City the right to remove any nuisance that might exist as soon as the Board of Health adjudged it dangerous, the question of compensation to the owner being left for subsequent adjudication by the civil court. Unfortunately this act was to have its provisions enforced only for three years. At the present time New York City is practically dependent on the State Commission of Health for the abatement of nuisances and this has introduced so much red tape into the procedures necessary to secure and enforce the removal of nuisances as to make our present laws for the protection of water supplies of the community generally more or less abortive.

Impossibility of Securing Conviction.—Mr. Walker presented the nine reasons why it is practically impossible to secure a conviction under the present law. First, the violation must be reported to the local Board of Health and a second warning must be sent to the violator; second, after a certain time inspection must be made to see if there is improvement in the matter complained of; third, in the absence of improvement the matter must be reported to the State Health Commission, which, as the fourth step, sends an inspector, who must report the matter back to them. Fifth, the State Commission warns the local health authorities; sixth, the local boards of health must convene and take cognizance of the matter and only then (seventh) is it possible to go on with their approval and secure the conviction of the offender. The corporation counsels office drew up two bills for the purpose of obviating these difficulties, but owing to an unfounded suspicion that somehow they had something to do with grabs with regard to the water supply of New York, these bills were not passed. At the present time it would seem eminently advisable to secure the repassage of the Webster act, by which the city could remove nuisances whenever they seem to become a menace to health and then pay such damages as should be adjudicated in the case.

State Commission of Health.—Dr. Daniel Lewis, the State Commissioner of Health, in discussing the subject of State control of water supply, said that the ownership of the Croton watershed, as far as is necessary to protect New York City's water supply, is being gradually acquired. He denied that the present laws cannot be enforced, since, in a number of cases, nuisances have been abated and other cities throughout the State are well satisfied with what they are able to accomplish, when they are really determined in the matter. Last year a number of infractions of the present law were reported to the Commissioners of Health. Within fourteen days, investigations were begun. Within twenty-one days reports of inspection were filed and if these cases had been prosecuted, as they should have been, undoubtedly greater respect for law would have been inspired, and it would have been easy by simple warnings to secure the abatement of other nuisances. As it is, for some reason or other the cases were not prosecuted and this laxity reflects back and makes conditions worse in the watershed.

The Other Side.—Dr. Lewis considers that the other side of the question should be considered, and that the mere fact that people are living along the watershed should not be supposed to compel them to take expensive measures for the protection of others without some due compensation. No allowance is made for improvements effected and it must not be forgotten that the present discussion is evidently not meant to apply so much to existing conditions but to future possibilities. If by proper treatment the people themselves can be got to cooperate with the health authorities then much can be accomplished without appeal to legal procedure.

Dr. Bensel, in closing the discussion, said in answer to a question from the president as to whether any of the streams in which oysters were placed for fattening purposes were ever used for drinking by the people who lived along the banks, that practically all of these streams were in direct connection with the waters in which the oysters grow, as indeed they must necessarily be for the dredgers to bring oysters up in them and that consequently because of mixture with salt water during

the inflow of the tide most of them were brackish and therefore undrinkable. This, however, actually added to the danger as far as oysters were concerned, since, if any of the streams were used for drinking purposes the inhabitants along the banks would be much more careful with regard to the keeping the water free from sewage contamination. At the present time no attention seems to be paid to this matter and it does not seem to be considered as of any importance.

Dr. William H. Park said that in the matter of milk inspection and the improvement of the milk supply of New York City, the New York State Commissioners of Health had been very helpful and far from putting any obstacles in the path of the special milk commission or of the city Board of Health, they were ever ready to accord inspection privileges.

Dr. Darlington said that the city was indeed to be congratulated on the active workers of the Board of Health whose work he was just beginning to appreciate properly, while the State Commission of Health deserved all praise for hearty co-operation.

Prosecution of Quacks.—Mr. Andrews, of the Medical Society of the County of New York, then made a report with regard to some recent prosecutions of persons who are practising without a license or engaged in the sale of nostrums that brought them without the pale of the law. The Society had endeavored to expose one Philip Koch who posed as the brother of Robert Koch, and pretended that he was a collaborator with the distinguished German bacteriologist in the invention of a so-called lung cure. This Philip Koch had gone to England during the session of a tuberculosis congress, some years ago, and having waited until Robert Koch registered, signed his name immediately below and then secured a photograph of the two names to be used for advertising purposes. His exposure had broken up his business, though the fact that he employed two registered physicians prevented his active prosecution. As the result of the Society's work, however, he is now behind prison bars for the violation of the Practice of Medicine Act in the District of Columbia. The Society has recently found a diploma mill in New York, run by one Dr Conrad, who has come to be known in medicolegal circles as Conrad II. Dr. Conrad was the president, secretary, office boy and faculty of a medical school. For $100 a diploma in osteopathy was given, and for $550 a diploma in medicine. He had two branch establishments in the city. From papers found in his possession at the time of his arrest it is evident that he drafted the osteopathy bill, which gave so much trouble to the medical society at the last session of the legislature.

CONGRESS OF INTERNAL MEDICINE.

Twenty-first Session, held in Leipzig, April 18, 19, 20 and 21, 1904.

Arteriosclerosis.—Marchand classifies under arteriosclerosis all those arterial changes which lead to a diffuse or nodular thickening of the walls, especially the intima, and which are usually followed by fatty degeneration, sclerosis and calcification. The process is chiefly a degenerative one, though inflammatory and productive changes are common. Simple hypertrophy of the media and syphilitic arteritis of the medium-sized and small vessels should not be included, as they form distinct and separate processes. In arteriosclerosis the connective tissue growth is mainly hyperplastic and the increase of elastic tissue occurs by a splitting off of new lamellæ from the hypertrophied musculoelastic layer of the aorta or the elastica interna of the other arteries. Arteriosclerosis results from the mechanical factors at work during abnormal vessel-strain; these factors are caused by increased filling of the vessels and temporary or permanent rise of blood-pressure. But added to this there is always some local or general weakening, induced by general malnutrition, toxic or infectious processes, hereditary tendency, influence of temperature, etc. Sclerosis marked by degenerative and inflammatory changes above all in the media and adventitia of the thoracic aorta is caused in many cases by syphilis and the name productive mesa-ortitis is often applied to this condition. The first signs of arteriosclerosis show themselves in the elastic fibers of the musculoelastic layer of the interna and of the media of the aorta and in the elastica intima of the medium-sized and smaller vessels. The superficial atheromatous degeneration of the intima of the aorta in young individuals is already part of the process. Secondary to the degeneration of elastic fibers there will follow a compensatory, circumscribed or more diffuse hypertrophy of the intima. If the arteries of the extremity are found diseased, it does not necessarily mean that the aorta or other vessels are involved in the process. Not rarely arteriosclerosis is complicated by hypertrophy of the left ventricle owing to increased circulatory resistance and renal sclerosis. The importance of splanchnic arteriosclerosis in bringing about cardiac hypertrophy has been overestimated.

The subject arteriosclerosis was also selected by Romberg, who says that the most deleterious effect of the vessel-lesions upon the circulation is the loss of elasticity. The impediment caused by this and by the narrowing of the lumen is then compensated for by aneurism or dilatation. More work is rarely required of the left chamber since all vessels are hardly ever affected; in advanced sclerosis of the splanchnic vessels and of the aorta without aneurism there is, however, a moderate hypertrophy. In 90 per cent. of uncomplicated cases the blood-pressure is normal. The most common complicating lesions are seated in the heart, but coronary sclerosis is present in only a certain percentage where there is angina pectoris and cardiac asthma. The remainder suffer from the non-typical signs of a chronic insufficiency. In the kidneys there is a tendency toward chronic interstitial changes, which, when fully developed, will again react upon the heart. Cerebral signs often suggest neurasthenia at first and may later pass over into a psychosis. Involvement of the sensory organs and of the gastrointestinal tract is less frequent. In certain cases the vessels of the lower extremity are principally involved, giving rise to the interesting symptom-complex known as intermittent claudication. Important etiological factors in general are bodily exertion and nervous influences, beside these, alcohol, tobacco, coffee and tea are injurious, chiefly owing to the fluctuations in blood pressure which they bring about. Beneficial agents are rest rather than exercise, sufficient sleep, change of climate, indifferent or saline springs, restriction but not abstinence from alcohol, coffee, tobacco and tea. The diet should be simple and regular, without excessive amount of meat and spices, and fluids need not be cut off unless there is a tendency toward edema. Attention to the stool is a matter of prime importance. In the early changes, especially in the initial cerebral symptoms, in angina pectoris, etc., iodide of potash is of signal service, yet this drug is unable to correct anatomical changes, so that too much should never be expected. Small doses (three times daily half a gram) are best. There are no other specific remedies, though saltpetre has been recommended. In treating the kidneys, the attention should be

directed toward the heart: here the dangers of increasing the pressure are not as great as generally believed, but excessive rises must be avoided. In beginning stages of cardiac insufficiency and during convalescence from severe disease, mild carbonated baths are often excellent.

Practical Importance of Measuring the Blood-Pressure.—In estimating the blood pressure, one must distinguish between temporary and permanent changes. Thus, temporary falls are common in acute infectious diseases, especially tuberculosis and after tuberculosis injections. In valvular disease, chloralhydrate reduces the arterial tension only slightly, and can thus be given for days without bad effects. A transient increase in pressure is seen after emotional disturbances, and after the use of tobacco and alcohol. Bodily exertion will raise the pressure much higher after the use of alcohol than before. On the other hand, permanent high tension is common in arteriosclerosis and chronic interstitial nephritis. In some cases of this kind, the red cells are increased up to eight to eleven million, and as many are found in arterial as in venous blood. Increased pressure with diminished number of red cells was found only in nervous individuals. In conclusion, F. Geisbock demonstrated an interesting case of general plethora with increased pressure but without arteriosclerosis.

Experimental Arteriosclerosis.—The effects of constant change in pressure is best seen in the experiments of Erb, Jr. Three drops of adrenalin 1-1000 were injected daily into the ear-vein of rabbits; after six weeks the vessels showed diffuse or nodular thickening with calcification. Another animal received 10 c.c.m. of adrenalin during two months; the autopsy revealed an apoplectic focus in the brain, aneurism of the aorta and thickening with calcification of the remaining vessels. Fatty degeneration could not be found with the microscope, but the intima was strongly proliferated.

Blood-Pressure in Arteriosclerosis.—High pressure always suggests arteriosclerosis, though not always present in the disease. Gröbel goes so far as to state that it always signifies the advent of an interstitial process in the kidneys. The treatment calls for a regular mode of life and careful avoidance of all measures which lead to fluctuations in pressure. There is as yet no remedy which permanently lowers the pressure—not even the iodides or nitrates act in this direction. In cardiac insufficiency, the speaker gives small doses of digitalis even where the pressure is high. Massage, baths and gymnastics are frequently indicated if employed judiciously.

Arteriosclerosis and Life Insurance.—In looking over the records of life insurances, Bahrdt finds that 22 per cent. of patients die of arteriosclerosis or its complications, while the mortality of tuberculosis is only 7 per cent. Arteriosclerosis seems to be increasing during the last two years.

Pancreatic Lesions in Arteriosclerosis.—Hoppe-Seyler reports 16 cases of extensive lesions in the pancreas incident to arteriosclerosis; among these, six with marked glycosuria. In some, the vessels were so altered that thrombosis and obliteration were common; the parenchyma generally shows a growth of connective tissue which extends irregularly between the acini and does not spare the islands of Langerhans. There seems to be a definite relation between the severity of the glycosuria and the amount of tissue destroyed.

Method of Measuring Diastolic Blood-pressure. The usual instruments generally register only the systolic pressure and a method for measuring both systolic and diastolic does not as yet exist. Strasburger believes, however, that the instrument of Riva-Rocci may be employed since the diastolic pressure may be recorded when the radial artery becomes smaller with gradually increasing compression of the brachial. The importance of measuring both is evident since their difference corresponds to the height of the pulse. By dividing this "pulse-pressure" by the maximum pressure, a "blood-pressure quotient" is obtained which will give an idea of the relative work of the heart, the condition of the vessels and the blood-supply of the tissues—factors which generally can be obtained only by opening the arteries.

Discussion on Arteriosclerosis.—Kisch refers to the frequent coincidence of arteriosclerosis with limomatosis. Such cases often die of cerebral hemorrhage; the warning symptoms are bradycardia and irregularity of the pulse. Klemperer has seen arteriosclerosis very often among physicians. The lime contents of the blood is irrelevant, milk is desirable, alcohol injurious. V. Noorden believes increase of pressure is often high and the cause of many disturbances. He recommends a five per cent. alcohol solution of nitroglycerin up to 10 milligrams daily. The lime-metabolism does not differ materially from the normal, hence calcareous food need not be interdicted. Schott has seen arteriosclerosis in disease of the aortic valves before the age of twenty. The blood-pressure is often normal or subnormal. The use of nicotine seems to be a very important etiological factor. According to v. Jaksch, the neurasthenic symptoms are a result of the disease. He warmly recommends carbonated baths, sodium iodide in large doses once or twice weekly, with food poor in salt. Digitalis is dangerous and nitroglycerin should be employed with caution. A. Frankel states that arteriosclerotic angina is often secondary to acute infectious diseases, but is never observed in children. Obstruction and thrombosis of the mesenteric vessel often gives a characteristic symptom-complex marked by intermittent abdominal colic. Digitalis and morphine are most serviceable for cardiac asthma or arteriosclerosis, but should be used carefully in angina pectoris. Carbonated baths are also risky, since they may increase the pressure.

Examination of the Heart.—The phenomenon of diastolic pulsation of the chest wall of cases of mediastino-pericarditis which had been subjected to cardiolysis has been the object of special study by Brauer. By constructing a kymograph which definitely registers the curve, he could determine that the up-stroke does not correspond exactly to the diastole, but occurs somewhat later. An accidental sound which was formerly regarded as a bone-sound could also be heard despite the fact that the sternum had been resected, so that it is probably an auricular or split second sound. Typical diastolic pulsation is also seen occasionally in cases of shrinking kidney with beginning decompensation, but the systolic portion of the curve is different.

New Method of Examining the Venous Pulse.—By means of Mackenzie's polygraph, Deutsch could register the venous pulse, liver pulse, and apex-beat synchronously with the radial pulse. In the jugular curve, a carotid wave was found; before this a presystolic auricular, and behind this a delayed, systolic ventricular wave. The relation in size between the last two waves gives an idea as to the stagnation in the right heart, the degree of tricuspid insufficiency and the effect of contraction of the right ventricle and auricle. A purely ventricular (systolic with one wave) venous pulse gives a very grave prognosis since it shows that the over-dilated auricle has ceased to contract.

Determining Size of Heart. Orthodiagraphy is the only absolutely safe and accurate method of determining the size of the heart, except where there is much enlargement toward the left. De La Camp has also had

good results with deep percussion combined with palpation; in three-fourths of the cases the error is not more than three-fourths centimeter. Auscultatory percussion is inaccurate, since heart-shaped figuures can be obtained almost anywhere on the chest, and after death, where the heart has been removed.

Vessels in Typhoid.—In typhoid, Wiesel commonly found the tunica media of the vessels affected. During the height of the disease all the vessels of the body may show an increase of intramuscular connective tissue, atrophy of the smooth muscular fibers, and changes in the elastic fibers. The latter resemble the lesions found in myocarditis after infectious diseases.

Circulatory Organs in Typhoid.—In 38 cases of typhoid, Ortner discovered a distinct accentuation of the second aortic sound during a certain phase of the disease. The real cause of this is probably a relaxation of the peripheral superficial and deep vessels which also shows itself in dicrotism, pseudocelerity and pulsation of the small arteries. This relaxation would normally bring about a fall in blood pressure; since, however, the pressure was found normal a compensatory contraction of the splanchnic system probably occurs where the second aortic sound is not increased and an increased activity of the heart where it is. Death in typhoid follows from vasomotor paralysis and severe changes in the heart-muscle. A hitherto undescribed symptom is dicrotism of the capillary pulse. Similar conditions are found in influenza, miliary tuberculosis, pyemia and secondary lues.

Studies on Heart Action.—In a patient who had been subjected to an extensive thoracoplasty, so that the left half of the heart was covered only by skin, A. Hoffmann could induce extrasystolic contractions by means of the galvanic current. Other changes in rhythm occurred under the same conditions as in frogs and other mammals.

Exploratory Puncture of the Skull.—Neisser warmly recommends the exploratory puncture of the skull by means of electric drill. With care the dura is not injured and the large blood vessels are avoided. The aspiration of "old blood" will speak for extra or intradural hemorrhage, clear, albuminous fluid for cysts and pus for abscess. In cysts, simple aspiration may bring about a cure. In abscesses with doubtful location, aspiration may decide in which lobe of the cerebellum or if in the temporal lobe. The method is not absolutely harmless, but will often be indicated.

(To be Continued.)

BOOK REVIEW.

ROENTGEN RAY DIAGNOSIS AND THERAPY. By CARL BECK, M.D. D. Appleton & Co., New York and London.

THIS work forms an addition to the number of textbooks which have already appeared on this subject, but is supposed to differ from them in that it treats the field from a strictly clinical point of view. Consequently we find about two-thirds of the book given over to diagnosis of lesions in various parts of the body by the aid of the X-rays. This section is embellished by a large number of excellent illustrations original with the author. Considering the limitations of the half tone process, they are very good and in a work of this kind form one of the most important adjuncts in elucidating the text. The introductory section is devoted to the subject of technic and apparatus and a number of the author's devises are described. It seems that more attention might have been given to this section, as considerable doubt exists in the minds of most practitioners as to the necessary apparatus and its application. At the end of the book is appended a discussion of the other forms of light treatment, and in this the author states that in his opinion the Finson cannot, in its present stage of development, compete with the Roentgen method in value. It seems to us, however, that the status of these various agents is still too unsettled to admit of drawing any definite comparisons; it is probable that a limited field will be found for each. On the whole, the book may be regarded as an excellent introduction for the general practitioner of the value of this therapeutic agent, which has not yet been sufficiently recognized. He can feel, moreover, that the matter presented is based on painstaking research, for the author is an acknowledged authority in this field, was one of the earliest investigators in this country of the method and has most extensive personal experience.

BOOKS RECEIVED.

The MEDICAL NEWS *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* MEDICAL NEWS *will shortly appear.*

ORIGINAL ARTICLES.

HOME TREATMENT OF TUBERCULOSIS BY MEANS OF HOSPITAL DISPENSARIES.[1]

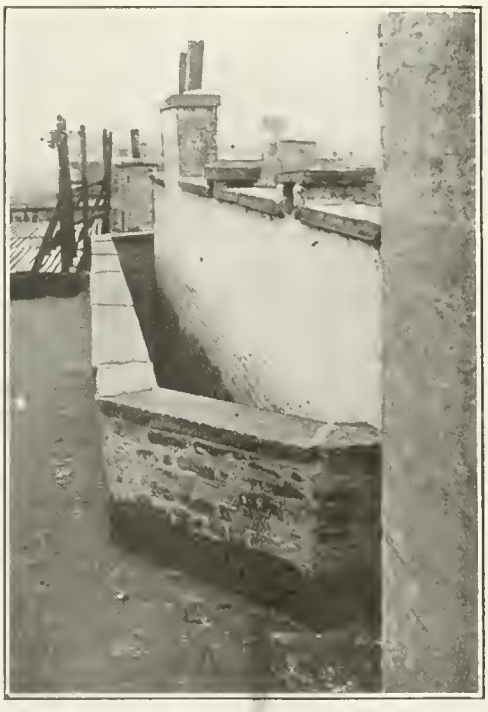
BY JOHN W. BRANNAN, M.D.,
OF NEW YORK.

THE gentlemen who were present at the meeting of this Association last year will remember the paper by Dr. Otis, on Dispensaries for Tuberculosis and the interesting discussion to which it gave rise. Unfortunately for myself I was not present at the reading of the paper, but entered the room as the discussion was closing. Dr. Otis, however, kindly sent me a copy of the paper soon afterward, and I was so much impressed by it that I at once set about establishing clinics for tuberculosis in the out-patient departments of Bellevue and its allied hospitals. At that time cases of tuberculosis in those hospitals, as in hospitals generally, were treated by those in charge of the general medical clinics. Dr. Otis and some of the other speakers last year referred to the difficulties they met with in organizing a special dispensary for tuberculosis. The chief difficulty in my experience was in finding properly qualified men who were willing to devote themselves to a clinic limited to tuberculosis alone. Finally, however, I succeeded in securing the man who was probably the best fitted of any physician in New York to take up this new work, Dr. James Alexander Miller. Dr. Miller, some six months before, had established at the Vanderbilt Clinic, at the instance of Dr. Walter B. James, a system of more careful management of cases of tuberculosis than had before been customary.

Fig. 1.

Bedroom from which patient was removed to No. 3.

Fig. 2.



Air shaft supplying light and air to bedroom in No. 1, at bottom of this shaft.

The main features of this system were special histories and regular weekly records of all cases, detailed oral and printed instructions in regard to the disease, free distribution of sputum pouches, and a visiting nurse, who made written reports of the home conditions and cooperated with the physician to make these conditions conform as far as possible to the hygienic requirements for the treatment of this disease. With

[1] Read at meeting of American Climatological Association at Philadelphia, June 3, 1904.

the kind permission of Dr. James, who recognized the larger field we had to offer, Dr. Miller came to Bellevue. He brought to us not only the experience acquired by him in the Vanderbilt Clinic, but also the interest and enthusiasm which, as Dr. Otis has said, are so necessary in this work. In return, we have placed all the re-

Fig. 3.

Bedroom to which patient was removed from No. 1.

sources of the hospital at his disposal, so that in addition to the means made use of at the Vanderbilt Clinic, he is supplied with milk and eggs for such patients as cannot afford to buy the extra nourishment required, and also the tent cottage that is shown in the photographs. The tent is in the open grounds of the hospital, upon

Fig. 4.

Patient on fire escape.

the banks of the East River, and is designed for those patients whom it is desirable to keep in bed because of elevation of temperature or for other reasons, or for whom a few weeks' training in habits of life seems desirable.

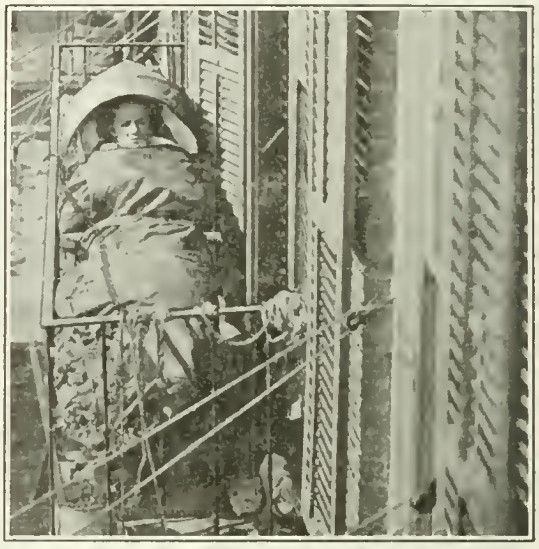
Dr. Miller has recently prepared a report of the work of the tuberculosis clinic for the first four months of this year, to be published in the Annual Medical and Surgical Report of the Hospital, and a summary of his observations may be of interest. The objects of the Tuberculosis Clinic as stated by him are as follows:

1. *Careful and Thorough Medical Attention* to each patient in a separate clinic by physicians especially interested and experienced in this disease.

2. *Systematic Investigation and Supervision of the Home Conditions* of each patient.

3. *Education of the Patients and Their Families* in the principles of good hygiene and the prevention of the spread of infection.

Fig. 5.



Another view of patient on fire escape. (See Fig. 4.)

4. *The Study of the Social and Economic Conditions in* connection with the medical aspects of each case and the relief and amelioration of those which are unfavorable.

5. *The Opportunity for Scientific Investigation* and clinical experience for physicians and students.

Fig. 6.

Patient in hammock on roof.

Taking up these objects in turn, let us see what has thus far been accomplished.

1. *Careful Medical Attention.*—When a patient is referred to this clinic he is sent to a

separate room for tuberculous patients, the temperature and pulse are noted by the nurse in attendance, and the history is taken by one of the physicians upon special forms upon which all the points to be investigated are printed. A careful examination is then made, including chest measurements, laryngeal examination, if at all indicated, and careful weighing with the patient stripped to the waist. The results of this examination are recorded on the history sheet, the physical signs by the graphic method. A positive, or even probable, diagnosis being made, the name and address are given to the nurse as a case to be visited. The sputum is sent to the Department of Health for examination. The patient is informed of the nature of his disease, of the principles of its treatment, and the dangers of infection, and printed circulars of instruction are given him for reference. The general principles of fresh air, rest, and extra nourishment

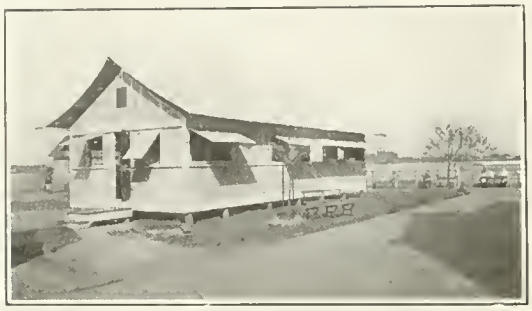
Fig. 7.

Patient in extension chair on roof.

are explained in detail. As a rule the diet advised is a mixed one, with two quarts of milk and four raw eggs additional each day. This number is gradually increased to the point of increase in weight or the tolerance of the individual, but the maximum quantity prescribed is about three quarts of milk and eight to ten eggs daily. The amount of fresh air and rest that these patients can obtain is, of course, very variable. It is almost always less than is desirable, but by persistent emphasis upon their importance much can often be accomplished.

Medication plays a minor rôle in the plan of management. Cathartics are most necessary during overfeeding, and stomachic tonics are very useful. Cod-liver oil is given freely as a food during the winter months. Creosote is very seldom prescribed. Symptoms such as distressing cough, pain, night-sweats, etc., must be relieved. The general principle, however, is to use as little medication as possible. Pocket sputum pouches, and more substantial ones for home use, are given to each patient from the drug room. Patients are requested to return to the clinic once a week and a record of their weight, temperature, pulse and general condition is made at each visit. Careful physical examination is made at least once a month, but, of course, as much oftener as any indication suggests.

Fig. 8.



Tent at Bellevue, showing proximity to river.

2. *Thorough Investigation and Supervision of the Home Conditions* of each patient. This is best accomplished by means of visiting nurses who have had special training in district nursing as well as hospital work. At Bellevue there are two such nurses, Miss Damer and Miss Hopkins. Both are graduates of the Bellevue Training School and both have been active and successful in district work, the former with the Buffalo Charity Organization Society, the latter with the Charity Organization Society of New York. Under their direction one of the pupil

Fig. 9.

Tent at Bellevue, looking west.

nurses also helps in this work, which thus becomes a part of her training. Each new case is referred to the nurse, with any special instructions or information that may be thought advisable, and, after a thorough inspection of the home, a report is made out by her upon printed forms provided for the purpose and submitted to the physician in charge of the case, together with any suggestions which may occur to her as a result of her visit.

The general plan is to arrange the whole domestic economy to the best interests of the patient

and to provide against the dangers of infection to his household and associates. Careful and detailed instructions are given as to ventilation and the principles of fresh-air treatment, and practical demonstration is made of the proper method of disinfection of the bed clothing, eating utensils, and personal linen of the patient; also any necessary suggestions are made along the lines of general cleanliness and better hygiene. Thorough inquiry is made concerning the care which the patient habitually takes of his expectoration, and notice taken of the general attitude of the whole household toward the instructions given at the clinic. Investigation is made into the available facilities for taking a "rest cure" out of doors, and the fire-escape, the roof, and the nearest park are all considered from this point of view, and the results incorporated in the report. For a few patients we have been able to secure sleeping bags, reclining chairs, or hammocks, so that they may stay out of doors almost continually. (See photographs 4, 5, 6, and 7.) The family resources are also noted and recommendations for assistance are made accordingly. Oftentimes the "home" is absolutely unsuited to our purpose; if so, it is so stated and the actual conditions existing are described. Photographs 1, 2 and 3 show how the home conditions of the patient may be bettered by simply moving him from a dark interior bedroom to the sunny parlor of his own apartment.

3. *The Education of the Patients* and their families in the principles of good hygiene and the prevention of the spread of the infection. How this is accomplished by the constant reiteration of sound advice from physicians, nurses and printed circulars is apparent. During the past four months our nurses have visited 138 patients whose aggregate families number 621. Each one of these individuals is now a center of information in regard to the general principles of healthful living.

4. *The Study of Social and Economic Conditions* obtaining in each case. This means the correlation of all the available data obtained from the investigations of the physicians and of the nurse. Upon this study the physician bases his method of management of each case. This involves upon the part of the physician an intimate knowledge of all available resources. In our work we keep in close communication with all the sanatoria and hospitals which admit tuberculous patients and attempt to send suitable cases to the institutions best adapted to their needs. The regulations of the Health Department and Tenement House Department are studied and observed; the facilities offered by the Charity Organization Society, the United Hebrew Charities, the Association for Improving the Condition of the Poor, the various churches and religious societies, the Diet Kitchen Association and the Straus Milk Depots are all well known and constantly utilized. In addition milk and eggs from the hospital storeroom are given free to such patients as are found to be unable to sufficiently provide for themselves. Lately a tent cottage has been erected upon the hospital grounds, accommodating twelve patients, which is for the use of those patients in the clinic whom it is desirable to keep under observation temporarily, or for favorable cases for whom proper sanatorium or home treatment is not possible. The proper use of all these means is an essential portion of the treatment, and the responsibility for it rests with the physician, from whom it requires careful study and judgment.

5. *The Opportunity for Scientific Investigation* and clinical experience for physicians and students. This portion of the work has not yet been developed. It is proposed to take it up systematically next autumn and it is hoped that tuberculosis will be studied in this clinic along various lines.

The activities of Dr. Miller have been, in the main, limited to Bellevue, but we have fortunately been able to find capable and well-trained physicians to take up the work at some of our other hospitals. This is particularly true of Gouverneur, where a tuberculosis clinic was organized last October by two young women physicians, Dr Stella S. Bradford and Dr. N. G. Seymour. As a result of their efforts the number of cases has grown from one or two a day to ten or twenty a day. During the month of April 24 new cases were enrolled. The methods of management are very much the same as at Bellevue, except that we have not as yet obtained a trained nurse to visit the patients regularly at their homes, but we hope very soon to supply this deficiency.[1] Dr. Bradford has just submitted a report on the work at Gouverneur, which will be published in our annual report, along with that of Dr. Miller. Working under trying conditions that would have disheartened most men, she and her colleague have accomplished results almost equal to those obtained at Bellevue. In commenting upon the intelligence of some of the population of the East Side, Dr. Bradford cites the cases of the man who with perfect equanimity upset his sputum bottle in his pocket, and the woman who, on being told to hold her hand before her face when she coughed, promptly spat into it!

At Harlem Hospital, where the dispensary service is very heavy, a separate clinic for tuberculosis was opened three months ago, but the number of patients does not yet compare with that at Bellevue and at Gouverneur. Fordham, our fourth hospital, lies in the outskirts of the city, where there are but few out-patients, and no attempt has yet been made to separate the tuberculous from the other patients. We have asked Dr. Miller to supervise the work at all four hospitals, so that each may profit by the experience of the others, and at our meeting of next year I shall hope to present a report of the

1 Since this paper was read an experienced nurse has been assigned to Gouverneur Hospital.

work more worthy of your attention than these rather disjointed notes of to-day.

I have been asked to say a few words as to results. Of course it is too early to talk of cures or even of arrested cases under a system of treatment which has been in force less than a year and with cases numbering less than 300. At Gouverneur, of the patients who have been under continuous observation, two-thirds have shown a gain in weight, and to-day I received a letter from Dr. Miller, in which he stated that of the patients in the tent cottage at Bellevue, all but one had gained from six to fifteen pounds in weight, with a corresponding improvement in all the other symptoms. The woman photographed in the steamer chair on the fire-escape had gained fourteen pounds in six weeks, though she had been considered a hopeless case. When in the course of the next year or two we shall be prepared to make a report, the results will no doubt be such as have been obtained elsewhere from the use of fresh air, rest and extra nourishment, combined with special study of the conditions of each individual case.

BONE AND CARTILAGE IN THE TONSIL.[1] [2]

BY JAMES E. NEWCOMB, M.D.,
OF NEW YORK;
CONSULTING LARYNGOLOGIST, ROOSEVELT HOSPITAL; CLINICAL INSTRUCTOR IN LARYNGOLOGY, CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK.

THE interest of the writer was first called to this subject some years ago by the paper of Stirling, hereinafter referred to, and a record has been made of the few instances of the condition since appearing in current literature. This interest was renewed two years ago by a personal experience, briefly as follows:

A woman of about thirty years, nurse, came for consultation in regard to frequent though slight sore throat. Examination showed moderately enlarged faucial tonsils. Their removal was advised and agreed to by the patient. The Mackenzie instrument was employed and the right tonsil removed without incident. A few days later the operation was repeated on the left side and as the blade of the instrument was driven home, the sensation was experienced of driving through some hard substance which, however, was easily pierced. Examination of the tissue removed revealed the presence of a small rounded tip of bone. Palpation of the tonsillar stump at once showed that this tip belonged to the styloid process, the remainder of which could be easily made out. It came nearly to the surface of the stump, but was covered thereby sufficiently well to prevent irritation, as was verified by a very recent examination. Palpation on the right side did not reveal anything abnormal. The case was therefore one of abnormal length and direction of the left styloid process, the tip of which had been removed by tonsillotomy.

Under normal conditions the styloid process has a length of 2½ cm. and extends from the under surface of the temporal bone downward, forward and inward. It is derived from the second branchial arch.

The recital of an unusual clinical experience is apt to start up other similar recitals, so that it soon becomes evident that a condition assumed by the first reporter to be rare is in reality quite common. It is not possible to say just how common the anomaly described really is. As a matter of fact but few instances are on record. One of the most striking is that of Richards, who, in the case of an elderly woman, found himself unable to sever the tonsil with a tonsillotome. Palpation showed a hard mass calling for the use of bone forceps. After this the tonsil was easily severed. The same condition, though to a less marked degree, was found on the other side. In Richards' case it was possible for him to detect bone marrow in the fragment removed. He appends a note from Prof. Thomas Dwight, of the Harvard Medical School, who states that ossification frequently extends down the stylohyoid ligament, thus apparently lengthening the process proper. To reach the level of the tonsil a length of from 5 to 6 cm. of bony structure would be necessary.

Three cases were reported by Stirling some years ago. Case I was that of a young woman with cheesy matter in the tonsilar crypts. On the right side there was a hard mass coming from behind the tonsil forward underneath it to the level of its anterior surface, ending in a point and forming a part of the side of the organ. The point was rounded and about an eighth of an inch in diameter, but broader and somewhat flattened laterally as it extended backward, outward and slightly upward. The finger in front entered the angle formed by it and the inferior maxilla and when pressed behind it entered another angle formed by its proximity to the right side of the vertebral column. There was present a tenderness from the pinching of the mucosa between the body and the finger. The second patient showed a slight protuberance just above and in front of the right tonsil; otherwise it was like the first case, but the condition was bilateral. The third patient was a brother of the second patient. Here also the condition was bilateral. The hard masses were altogether in the posterior portion of the tonsil and reached a level a full finger's breadth below the lower border of the organ. The mass in the third patient was more slender than in the other two cases, was distinctly cartilaginous in feel and was movable. In making his diagnosis, Stirling excluded calculi as not giving the conditions present; the masses might have belonged to the jaw but did not move with it. The finger could exclude the vertebral bodies. The masses were too far forward to come either from the base of the skull or to be regarded as spines on the posterior portions of the sphenoid wings. He concluded that they must be either the transverse processes of the vertebræ or the styloid processes and finally decided in favor of

1 Paper presented at the Twenty-sixth Annual Congress of the American Laryngological Association, held at Atlantic City, June 2 to 4, 1904.

2 Received for publication May 31, 1904.

the latter. He found one reference to the condition in Schech's book and references by the latter author to cases reported by Grube, Lücke and Weinlechner, but these reports were not accessible to the writer.

I do not know that any great importance attaches to the condition unless the projection should be long enough and the direction of the styloid process oblique enough to cause tonsillar irritation. In most, if not all, the cases reported the abnormality has been discovered accidentally. If after tonsillotomy the stump should not be sufficiently padded by the soft tissues there might be a condition awkward to relieve, but such relief could undoubtedly be afforded by the use of bone forceps, as in Richards' case. In the comments of Professor Dwight on Richards' case he notes that "it is perfectly in accord with all we know of the process of growth of organs that if a bony structure should encroach on the domain of adenoid tissue the latter should, so to speak, fold itself around it."

When we come to the question of bony deposits scattered through the tonsils we find a more voluminous literature, as the subject has been considered by several authors who have also found cartilage and have considered the two conditions together. Personally I have removed tonsils which on inspection showed masses too large and too hard to be regarded as foci of connective tissue and I have surmised that they might be cartilaginous, but this view has never been confirmed by microscopical examination.

Several years ago Walsham reported two cases bearing on this matter. The first patient was a man of fifty years whose senile tonsil showed scattered through it, at the base of the crypts, numerous small bony masses in the shape of nodules, rings and trabeculæ. They did not encroach on the lymph structure of the organ. The second case was that of a patient with an atrophied tonsil, a man of twenty-seven years. Through the lymphoid structure of the organ were scattered masses of cartilage large enough to be detected by the eye. In places it had been converted into bone. The matrix appeared sometimes hyaline, at other times fibrocartilaginous. The cartilage was in the form of nodules surrounded by strands of dense fibrous tissue which formed a sort of perichondrium. Some penetrated the lymphoid tissue and in one place they nearly reached the epithelial covering. Walsham regarded them as enchondromata, finding a close analogy between them and the small cartilaginous growths which sometimes develop about the branchial clefts and which are also found in the neighborhood of the ears; also analogous to the cartilage found in the parotid gland.

According to His, the tonsil is developed in the fourth month of fetal life by a simple infolding of the mucosa at a spot between the second and third branchial arches. This site remains visible in the adult tonsil as the operculum or triangular fold, which frequently extends over from the anterior faucial pillar, veiling the tonsil's antero-lateral aspect. As development progresses the primary infolding, which is the original lacuna, splits at its base into secondary lacunæ and the fully formed organ results from the swelling of the mesoblastic tissue and the early appearance of the lymph follicles. According to this view, the cartilage is of fetal origin, *i.e.*, is the vestigial rest of the second branchial arch. From this view Kanthack dissents, regarding the cartilage merely as a metaplasia of fibrous tissue. The enchondromata result from the starting up to renewed growth of these vestigial rests.

Walsham was able to find two similar cases reported by Roth and one by Deichert, who himself knew of two other cases. Walsham found the condition twice in thirty-four autopsies.

Wingrave found cartilage three times in examining two hundred tonsils. He regarded these deposits as identical in formation with the subpharyngeal cartilage of Luschka. As did Walsham, he found hyaline and white fibrocartilage imbedded in a dense connective tissue capsule, sometimes in the fibrous bed, sometimes in the lymph pulp of the organ. In one instance the cartilage was calcified.

Nösske found multiple bone and cartilaginous deposits in the deeper layers of connective tissue coating the tonsil. There was almost always a connection with the surrounding connective tissue as well as numerous transition pictures between the two. This author would include in etiology, inflammation, retrogressive changes and a sort of local predisposition.

Petroff examined the tonsils excised from a patient who had died of pulmonary tuberculosis, finding tuberculous foci and cartilaginous deposits as well. Further investigations on 40 tonsils removed from 22 cadavers of both sexes and varying ages revealed cartilage and bone in eleven, cartilage alone in ten and bone in one. All the tonsils showed a fibrous degeneration. He regarded the condition as due to a chronic inflammation with proliferation of connective tissue and deposit of lime salts.

Reitmann refers to the work of Pollak, who explained the formation of bone on the basis of "cretification" of tuberculous foci after an inflammatory process. To the process he gave the formidable name of "Amygdalitis hemorrhagica interstitialis chronica ossificans." Reitmann himself refers to 12 cases collected by various authors and examined three human embryos together with 50 tonsils removed from 37 individuals, the age limits being an embryo of thirteen weeks and a living patient of sixty-five years. Of the tonsils, 17, or 34 per cent., gave a positive result, showing that the condition may be more frequent than is generally supposed. His general conclusions are as follows: Cartilaginous nodules or their derivatives occur in the tonsils or surrounding tissues. They are generally hyaline, rich in cells but poor in basement substance, that is, resemble embryonal cartilage. In two instances retrograde changes were evident. Various stages of transformation from bone to cartilage

were found. Cartilage always lies free from any attachment to the skeletal frame. The condition found in one of the embryos allowed him to believe that he had to do with a derivative from the second branchial arch, arising not in continuity but as an offshoot. He does not regard this theory of origin as positively proven by any evidence thus far brought forward, nor is he certain that these vestiges can serve as a starting point for either enchondromata or osteomata.

Very recently Zuckerkandl has stated that cartilage develops independently of the skeleton in the connective tissue of organs when mechanical relations demand the presence of such tissue, as for instance in the Eustachian tube. In many of the lower orders of life only fibrous tissue is found in this latter structure. He reports the interesting fact of finding in a pharyngeal tonsil removed from an adult lion, first, a superficial adenoid layer; second, a connective tissue layer, and third, glands between the two. In the connective tissue layer cartilage were found between the glands and follicles. It is not a constant feature in this animal as it was absent in a dead-born animal and also in an embryo.

An interesting case has been studied by Rosenberg and Töpfer, the former reporting the clinical and the latter the histological details. A peculiarity of the case was that it was the first one in which muscular fibers were found in the tonsil. They appeared in the connective tissue capsule of the organ and certain of them had thrust themselves into the trabeculæ running in from the capsule. Töpfer considered them as belonging to that group called "musculi tonsillares," which normally are on the outside of the capsule. The tonsil showed hyperkeratosis and it is surmised by the writer named that the fibers were the cause of irritation to the tonsilar substance resulting in the hyperkeratosis. In the same organ were found foci of hyaline cartilage in the connective tissue portions. Against the theory that these were due to developmental disturbances during fetal life, that is, of the branchial arches, is the fact that first development of the tonsil begins between the fourth and fifth month, at a time when little or no vestiges of the branchial arches remain. Moreover, the cartilage was found in the purely connective-tissue portions only of the organ, never in the lymphoid pulp and, finally, the deposits were multiple. In a second tonsil, two larger deposits were found and here could be recognized the transition stages in the change from connective tissue to cartilage. The fibers of the latter separated, allowing the cells to project, then swelled, forming a network in the meshes of which were the cartilaginous capsules in which the cells lay. These had gone over from the spindle-shaped to a more polygonal form. How long this process may require, and what is its exciting cause, we have no means of knowing.

Töpfer observes that if the cartilaginous foci are merely aberrant deposits from the branchial arches we ought to find them in all sections of the organ, but we do not so do. Or, it might be supposed that they had spread out through the tissue into which they had grown. Against this view was the fact that each deposit stood by itself with its fibrous envelope, that is, the assumed perichondrium, but everywhere there was a certain connection between the cartilage and its connective tissue environment. Hence Töpfer's main proposition is that the deposits result from connective tissue metamorphosis. In some sections the transition seemed to have gone farther than above described, so that it appeared as if the groundwork of bone had been laid down preparatory to the deposition of lime salts.

With certain staining agents pictures were seen suggesting an earlier colloid state, later a mucoid state. It is difficult to say whether or not this mucoid stage is a transition between colloid and the material out of which hyaline cartilage is formed. The whole process may be a retrograde one, that is, the retrogression of cartilage into mucoid material. Evidence suggesting this was found in the fact that in the middle of the areas out of which the cartilaginous deposits originated, there was a focus of softening or a small hollow filled with mucin and some round cells.

This transition from connective tissue to cartilage is not, according to Töpfer, to be looked on as a late or senile change in the former, for the same process has been found in children. Since the deposit comes from a cartilaginous matrix, it must be regarded as an enchondroma, while the hyperplastic mass from which comes the pre-existing connective tissue is an ecchondrosis.

The author just named thinks that the results of examination of tonsils vary according as the organs are removed from the cadaver or the living body. Virchow has suggested that the connective tissue which has newly formed itself as the result of chronic interstitial processes is the matrix of the later enchondroma. Owing to the numerous inflammatory processes going on in the tonsils it is conceivable that cartilage should arise on the same basis. Wingrave found cartilaginous nodules in chronic hyperplastic organs, but other observers have found them in normal organs.

Finally, it may be noted that the Eustachian tube is formed from the first branchial arch; a portion of the cartilage might be shut up in the tonsil, since, according to Kölliker, the first position of the tonsil is in a line with the tube, but somewhat more dorsal. Zuckerkandl found cases showing cartilaginous nodules in the vicinity of the tubes, especially in the salpingopharyngeal ligament.

THE DISTINCTION BETWEEN FRACTURE OF THE NECK OF THE FEMUR AND EPIPHYSEAL DISJUNCTION IN EARLY LIFE, WITH REFERENCE TO ITS INFLUENCE UPON PROGNOSIS AND TREATMENT.[1]

BY ROYAL WHITMAN, M.D.,
OF NEW YORK.

My contention that fracture of the neck of the femur is relatively common in early life, is now generally admitted, but there is a strong tendency among German writers to class these cases as epiphyseal separations rather than simple fractures. Hoffa, for example, in a recent article (*Zeitschrift f. Ortho. Chir.,* Vol. II, 1903), has collected eighty-four cases from literature, including ten reported by me in 1897. Of these but four are admitted to be true fractures. In other words he would consider all cases of this type as epiphyseal fractures, unless it can be directly demonstrated, as by operation or autopsy, that the injury is not at the epiphyseal junction.

It might seem perhaps that as both forms of injury are properly classified as fracture, the exact situation is unimportant. In fact, I should not again protest against this classification, however unwarranted it may be by the evidence were it not that an accurate diagnosis may have a deciding influence upon the treatment. It is well known that epiphyseal disjunctions in other situations are uncommon as compared with fracture in early life, as is well illustrated at the elbow-joint. It is difficult to produce an epiphyseal disjunction experimentally, even when the force is adjusted with this end in view. If then, epiphyseal separation is relatively so common at the hip-joint, it can be explained only by anatomical or pathological predisposition. Anatomically there is no predisposition, since the neck is much smaller than the junction. Even when fracture occurs during the reduction of a congenitally displaced femur, the manipulation which of all others should induce separation, the clinical evidence is in favor of fracture of the neck. And this fracture was demonstrated in the only case that to my knowledge has come to autopsy. (Wilson and Rugh, *Am. Jour. Ortho. Surgery,* February, 1904.)

An epiphyseal junction is not a weak point in the bone during childhood unless as the effect of local or general disease. It is however, relatively weak in adolescence, as the period of consolidation approaches, when the protecting rim of cartilage which covers it has been reduced to an approximately adult thickness. In fact, it will be found on investigation that nearly all the anatomical evidence in favor of epiphyseal separation dates from the two cases reported by Sprengel, (*Archiv für klin. Chir.,* B. 47, 1898, S. 805.), of patients aged respectively seventeen and eighteen years, and is of similar character, that is to say an evident predisposition to this particular form of injury was present.

[1] Read before the American Orthopedic Association, June 9, 1904.

Admitting that either epiphyseal separation or fracture may occur as the result of violence, the following are the chief distinctions between them, and in introducing the subject it should be stated that although complete fracture and, in rare instances, complete separation of the epiphysis may occur, it is far more often incomplete and it is this class that is under especial consideration.

Fracture of the neck of the femur is usually the result of direct violence. The majority of the patients are healthy children. The disability is immediate; it lessens as repair proceeds and in a few months the patient may be practically well except for a slight limp and limitation of motion dependent upon the depression of the femoral neck (traumatic coxa vara). Epiphyseal disjunction is usually a more gradual process. The patients are almost always adolescents, very often of the overweighted or overgrown type. The injury is often slight, of the nature of a twist or strain or misstep, so slight in fact that it may pass unnoticed. The first symptoms are limp, slight stiffness, and discomfort rather than pain referred to the hip and thigh. These symptoms may persist for weeks or months then, usually after overexertion or other injury, the disability may suddenly increase, an indication of a more extensive secondary fracture.

It may be noted then that in childhood fracture of the neck of the femur caused directly by violence does not differ essentially in its history or symptoms from impacted fracture in the adult, except that the disability is less and recovery more rapid. On the other hand, the characteristic symptoms of partial epiphyseal separation and the class of patients in which it is most common resemble closely those of adolescent coxa vara.

There is also a well-marked distinction in the physical signs. In traumatic depression of the neck of the femur, there are shortening and outward rotation of the limb with elevation and prominence of the trochanter. Motion may be practically free except in abduction which is much restricted, particularly when the limb is flexed.

In partial epiphyseal separation the outward rotation of the limb is more marked, but the shortening is less, usually not more than half an inch. As a rule the limb is completely extended and in many instances a resistant swelling is apparent in Scarpa's space. The trochanter is not as prominent, but motion is much more limited than in fracture. In many instances it is almost completely restricted by muscular spasm, and there may be effusion within the joint and sensitiveness to pressure.

The distinction between the symptoms and physical signs in the two classes of cases may be explained by the situation of the injury and its effect upon the function of the joint. If the neck of the femur is forcibly depressed as the effect of an incomplete fracture at some distance from its articulating extremity, motion, when repair is advanced will not be restricted other than by the distortion of the neck, thus primarily in abduction, inward rotation and, to some degree, in

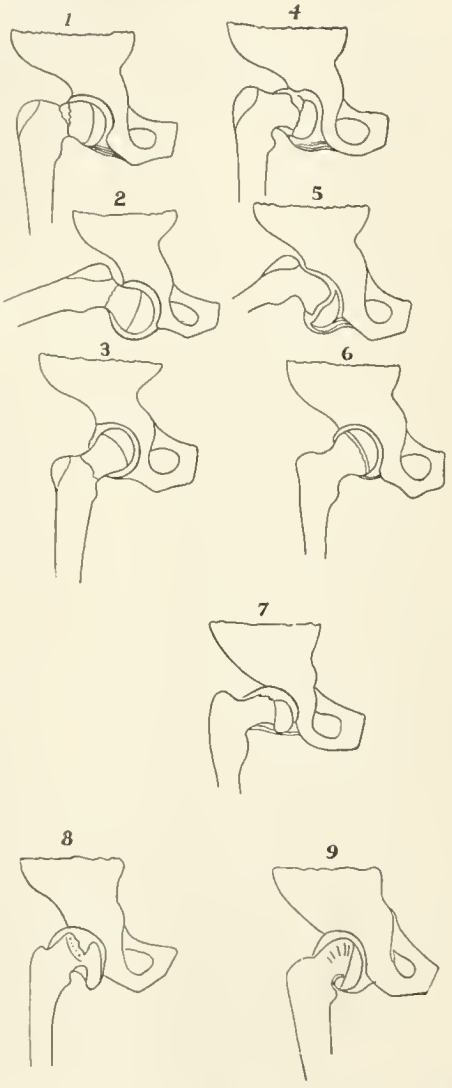
flexion. Corresponding to the depression of the neck there are of course shortening of the limb and an abnormal projection of the trochanter, which may be made more noticeable by flexing and adducting the thigh. If, however, the epiphysis, forming the cartilaginous extremity of the bone, be displaced, as it usually is in these cases, downward and backward, there is direct interference with the movements of the joint, increased by the sympathetic irritation about the injured part. The neck of the femur projects from the shaft at the normal angle. The epiphyseal extremity remains within the acetabulum and it is the upper and anterior extremity of the neck that forms the projection in Scarpa's space.

In some instances the downward displacement of the epiphysis which is still firmly adherent to the neck, may not be greater than a quarter of an inch, and although the characteristic symptoms may be well marked, shortening may be practically absent. Even in these early cases the muscular spasm may be so great that the joint may be practically fixed. The symptoms in fact, very closely resemble those of disease of the joint except that the limb is usually completely extended and pain is absent when the patient is at rest; whereas flexion is the almost invariable attitude of disease and neuralgic pain is a common symptom. In this class of cases the original injury may have caused simply a rupture of the protecting covering at the epiphyseal junction, and in the absence of further injury it is possible for complete recovery to take place. In most cases, however, as the patient continues to use the limb, this displacement is progressive, being accompanied by a process of partial repair; thus the head of the bone is usually firmly adherent to the neck.

It is apparent that the history and the symptoms that have been described resemble those of coxa vara rather than of the ordinary form of fracture. It may be mentioned also in this connection that there are two classes of coxa vara, one in which the entire neck is depressed, and the other in which the deformity is in the newly formed bone on the outer side of the epiphyseal cartilage. In this latter class the symptoms may be aggravated by actual fracture at the point of weakness, and in such cases it is practically impossible to distinguish accurately between these and true primary traumatic epiphyseal separation. In fact, it is probable that many of the cases reported as epiphyseal separation are of this type.

In many instances it is possible to demonstrate the seat of the injury by means of the X-ray. In ordinary fracture the neck as a whole is depressed, while in epiphyseal separation one can often distinguish the neck projecting at a normal angle from the shaft, the deformity showing clearly at its inner third.

One may conclude then that when fracture at the hip-joint follows a fall from a height, or other considerable violence, the injury, as in older patients, is usually of the middle or outer portion of the neck. In adolescence on the other hand, when progressive disability follows slight injury and when the physical signs are similar to those described, one may suspect fracture at the epiphyseal junction.



1. Fracture of the neck of the femur. 2. Restoration of the normal angle by forcible abduction. 3. The limb in normal position. Figs. 4, 5 and 6 illustrate complete separation of the epiphysis of the head of the femur treated by the same method. 7. Illustrates slight separation in which protection might assure a satisfactory result. 8. More extreme displacement, that can only be treated by direct operative reposition. This contrasted with fracture of the neck (Fig. 1) illustrates the greater disturbance of joint function that must inevitably result. 9. A form of epiphyseal coxa vara often induced or aggravated by injury in which the deformity is most marked on the outer side of the epiphyseal cartilage.

As has been stated, the importance of an accurate distinction between the two forms of injury may have a direct influence upon treatment, assuming that its object is the restoration of normal form rather than palliation of the symptoms. If the neck of the femur has been forcibly depressed and partly broken through, the rela-

tions of the head of the bone and the acetabulum are not particularly disturbed. If then, one has the opportunity to treat such a case before consolidation is completed one may, by forcibly abducting the thigh and utilizing the upper border of the acetabulum as a fulcrum, actually restore the normal angle. If the limb be fixed for a sufficient time in a plaster bandage at the limit of normal abduction, anatomical and functional cure may be assured. Or, if consolidation is complete, one may, as in simple coxa vara, restore proper elevation of the neck by the removal of a wedge of bone at the base of the trochanter. Both of these procedures have been described by me in papers read before this society.

The importance of remedying depression of the neck of the femur which usually leads to progressive distortion, as contrasted with palliative treatment by support, is sufficiently evident. If, on the other hand, the articulating extremity is actually displaced, even to the extent of one-third of its area, the mutual relations of the bones are so disturbed that the function of the joint is seriously impaired. In such cases, as has been stated, the displacement is usually so gradual that it is accompanied by partial repair; it seems hardly probable therefore that forcible abduction could have very much effect in directly reducing the displacement. In this class of cases direct operative intervention is the treatment of selection, except in those unusual instances in which the displacement is so slight that it does not materially interfere with function. In cases of this character, support during the period of weakness would assure a cure. This emphasizes the importance of a careful examination in all cases of injury at the hip joint in childhood.

Operative treatment in this class should be directed to the exact replacement of the head of the bone, or, in the slighter cases, to the removal of the angle formed by the inner extremity of the neck which interferes directly with flexion. The treatment of the two forms of injury may be illustrated by cases where it has been applied.

Case I.—A boy, eight years of age, was brought to me by his family physician in October, 1901. Three weeks before he had fallen a distance of fifteen feet injuring the left hip. A few days later he was able to limp about, but there was no further improvement. On examination the typical symptoms of fracture were present, viz., the trochanter was elevated and prominent, there was one-half an inch of actual shortening and marked limitation of abduction. When the patient was anesthetized abduction was found to be limited to one-half the normal range by direct bony impact. Under traction the limb was slowly and forcibly abducted to the normal limit, the resistance giving way under direct pressure. The limb was fixed by a plaster bandage in the attitude of extreme abduction. In a few days the patient began to walk about and at the end of four months, when the spica was removed, the X-ray picture showed a restoration of the normal angle. Later examinations have demonstrated a functional and anatomical cure.

Case II.—A girl, six years of age, was seen in August, 1902. Three weeks before this time she had fallen from a second story window and as complete disability persisted she was brought in arms to the Hospital for Ruptured and Crippled. The physical signs, the treatment and the final results were practically identical with those of the previous case.

Partial traumatic epiphyseal separation may be illustrated by two cases which will demonstrate the contrast both in symptoms and treatment.

Case I.—A girl, fifteen years of age, began to limp and to complain of stiffness about the right thigh. No cause could be assigned other than a slight fall which was not accompanied by immediate symptoms. Eight weeks later, as the disability became more marked, she was admitted on November 23, 1903, to the Hospital for Ruptured and Crippled. The patient was of the overgrown adolescent type. The disability was complete, the limb was fixed in extension and rotated outward, there was marked muscular spasm with pain on passive motion. The shortening was not greater than a quarter of an inch. Diagnosis of partial epiphyseal separation was made and the joint was opened by the ordinary anterolateral incision. The epiphyseal extremity of the femur was found to be displaced downward and backward for about a quarter of an inch, exposing a sharp angular projection of the extremity of the neck. There was congestive synovitis which accounted for the muscular spasm, and the projecting bone interfered directly with the movements of the joint, particularly in flexion. This projection was removed with a chisel, the wound was closed and a plaster-of-Paris bandage was applied. This was removed six weeks later and the patient began to go about on crutches. At the end of three months she was allowed to use the limb and at the present time there is no disability on walking. Flexion is still limited, but not to a sufficient degree to interfere with function.

Case II.—This patient, a tall boy fifteen years of age, was dragged for half a block by a street car. He suffered more or less discomfort about the right hip, but continued at his daily work for two months when the stiffness and limp had so increased that he was practically disabled. He was admitted to the Hospital for Ruptured and Crippled on December 28, 1903. A diagnosis of epiphyseal separation was made on the following grounds: One-half an inch of shortening, marked outward rotation of the limb, which was fixed by muscular spasm in an attitude of extension, a resistant swelling was apparent on the anterior aspect of the joint. The joint was opened by the anterolateral incision and the inner extremity of the neck, which had caused the swelling already mentioned, presented itself. On extreme outward rotation the upper and anterior portion of the cartilaginous covering which had been displaced downward and inward could be

seen, still firmly adherent to the under third of the neck. A section of bone was removed from the neck, sufficient to allow a thin chisel to pass between it and the head. With this the epiphysis was completely separated and while it was pressed forward the limb was rotated inward until the head was exactly replaced. The wound was closed and a plaster-of-Paris bandage applied. At the end of six weeks the boy was allowed to go about on crutches, and soon after the plaster bandage was removed. The limitation of movement that followed the operation gradually lessened, and at the present time there is complete anatomical and functional cure.

These contrasting cases illustrate the importance of exact diagnosis and appropriate treatment, since it is evident that forcible abduction would have been useless in the cases of epiphyseal separation and that the open operation would have been unnecessary in the cases of fracture of the neck of the femur. The ease with which the head of the femur was replaced in the second case of epiphyseal separation and the complete cure that followed, indicate that this operation should always be performed, at least in recent cases, rather than excision, the routine operation of German surgeons, which from the functional standpoint must be ultimately disappointing in its results.

It may be noted that while it should be easy to distinguish ordinary fracture of the neck of the femur from epiphyseal separation it may be impossible to differentiate the latter from epiphyseal coxa vara which is most often seen in adolescence. The essential anatomical difference is this: in epiphyseal separation directly caused by injury there is, it would appear, a sliding downward of the head including the epiphyseal cartilage, exposing a sharp angle at the inner extremity of the neck; in epiphyseal coxa vara the deformity is in the newly formed bone on the outer side of the cartilage, similar to adolescent knock knee, a deformity rather rounded than angular. Such deformity although it may not be caused by injury may be aggravated by it, even to the extent of actual fracture through the weakened bone. The principles of treatment might be essentially the same as in traumatic cases, but the prognosis would be of course less favorable and the mechanical treatment must be of longer duration. It would appear that in any form of coxa vara, the line of the epiphyseal cartilage is changed from a direction from without inward, to one above downward, thus predisposing to injury.

I do not at this time propose to discuss the subject of coxa vara in general, but it would appear that while rachitis, present or remote, is practically always the cause of bilateral coxa vara, injury as an exciting or aggravating cause of the unilateral form is far more important than is generally believed.

One may include under fracture of the neck of the femur in early life three classes of cases: (1) Simple, direct fracture of the neck, usually incomplete, occasionally complete. (2) Direct epiphyseal disjunction, usually incomplete, in rare instances, complete. (3) An indefinite class, in which the deformity is at or in close proximity to the epiphyseal junction. The patients are of a type in which the so-called static deformities of adolescence are common, and injury may be predisposing, aggravating or direct cause of the distortion.

Of classes 1 and 2, that is, of undoubted direct fracture of the neck of the femur, thirty cases have come under my observation. Five of these are classified as epiphyseal disjunctions. Three were males and two females. All were adolescents, the youngest thirteen years and the oldest sixteen. In three instances the nature of the injury was indefinite, apparently a slight fall. One patient was injured in a game of football, and one was dragged by a street car.

The twenty-five cases of facture of the neck of the femur present a decided contrast both as to age and character of the injury. Twenty were children from two to ten years of age. Five were adolescents, 11 were males and 14 females.

Nature of the Accidents.—One patient fell from a sixth story, two fell from fourth stories, one from a third story, two from second stories. Seven fell from heights of at least fourteen feet, four fell down flights of stairs. One was run over. One was knocked down by a street car. One was thrown from a carriage. One fell from a bicycle. One fell from a swing, and in three cases the history was indefinite. These patients were, almost without exception, healthy children. The accidents were severe, and the disability was immediate. In 22 of the cases the fracture was incomplete, in three it was complete.

The third class has been usually included under coxa vara, of which I have the records of 63 cases, 42 males and 21 females. Of the entire number but 12 were bilateral. Many of the cases were examined before the X-ray was available for diagnosis, but it is estimated that in about one-quarter of the cases the deformity was near the epiphyseal junction, and in many of these, it was presumably induced by injury,—epiphyseal fracture. The preponderance of males over females, and of unilateral over bilateral cases, is certainly significant as indicating the importance of injury in the etiology of coxa vara. If these indefinite cases are to be classified as primary epiphyseal fracture, it still further emphasizes the importance of injury as causing distortion of the neck of the femur.

In this connection attention may be called again to the fact that it is from this class particularly that the majority of the cases of epiphyseal fracture that have been reported has been drawn. It is in this class that the cases are so commonly mistaken for hip disease, and it is in this class that early diagnosis and protective treatment might be efficacious. It is perhaps, therefore, the one of greatest interest to orthopedic surgeons.

The object of this paper is to call attention to

two forms of fracture of the neck of the femur, of which an accurate diagnosis may have an important influence upon treatment. Simple fracture should be treated by fixation at the limit of normal abduction, an attitude which implies restoration of the depressed neck to its normal position.

Partial epiphyseal separation should be treated by direct operative reposition of the head. Excision, which is at present in such favor with German surgeons, should be an operation of necessity rather than of choice.

One should never be content with mechanical support however efficient it may be in relieving the immediate symptoms, for, recognizing the fact that normal function is dependent upon normal form, one should always aim to remedy deformity whenever it is practicable.

THE RECTAL ADMINISTRATION OF THE NEWER HYPNOTICS.

BY MORRIS MANGES, M.D.,
OF NEW YORK.

In an unpublished paper, read before the City Hospital Alumni Association in 1899, I presented the results of a rather extensive series of cases in which the newer hypnotics had been given in suppositories.

While the value of the rectal administration of opium and its derivatives, the bromides, chloral, etc., has long been recognized and appreciated, the newer hypnotics such as sulfonal, trional, hedonal, etc., have been rarely used in this way. Yet cases not infrequently occur when great good could be accomplished if these drugs could be administered in some way other than by the stomach.

By way of illustration I might cite a recent experience of this kind: I was asked by Dr. Cabot to see a young woman upon whom a cholecystectomy for acute gangrenous infection had been performed by Dr. Lilienthal, and who was in a desperate state on the third day after the operation. The patient was an intensely nervous woman, whose incessant vomiting threatened not alone the success of the operation from the continual tugging at the sutures, but her life from the exhaustion. She had an idiosyncrasy against morphine, bromides per rectum had been tried in vain, chloral could not be given and the condition of the stomach prevented the administration of any drugs. I advised the rectal use of twenty grains of veronal dissolved in some sherry and water; within an hour this quieted the patient and half an hour later she fell into a sleep, lasting ten hours, from which she awoke in a condition permitting her to take nourishment by stomach. The subsequent course of events was an absolutely uneventful and rapid convalescence.

While this case was an extreme one of its kind, yet cases often occur in which, for reasons which need scarcely be discussed in detail, the stomach or skin may not be the best available route for the administration of hypnotics.

It may seem strange that insoluble preparations like sulfonal, trional and other hypnotics should be absorbed by the rectum; but clinical experience proves that this is the case and that the speed of the absorption is about the same as that which takes place in the stomach, even when they are administered in cocoa-butter suppositories. To quote from my former paper: "All are not equally active, since I found that hedonal, chloralose and chloretone were so slightly soluble as to be practically worthless in this connection; on the other hand, sulfonal acted much more powerfully than trional. Heroin, chloralamide and phenacetin were also readily absorbed. The use of combinations of sulfonal, or trional, sulfonal and phenacetin gave excellent results."

The suppositories in all these trials were of the ordinary size (fifteen grains of cocoa-butter). No irritation of the rectum was ever observed.

I might add that most of these observations were conducted in the wards of the Mt. Sinai Hospital, and the fact that even in the unsuitable environment of a hospital ward the hypnotic effect could be obtained in a fair number of cases established the value and possibilities of this method of administration. My subsequent experience with the rectal administration of these hypnotics has confirmed these observations, and now that the list of hypnotics has been enriched by the addition of veronal, which is distinguished from the others of this group by its free solubility, the value of this method of administration deserves to be more clearly recognized than it has been.

For rectal use veronal need not be administered in suppository form, but in solution either in warm milk, or preferably, in diluted sherry, to which a little salt or sugar has been added to increase the speed of absorption. The dose of veronal for this purpose is somewhat larger than when administered by mouth, the average dose for an adult being fifteen to twenty grains.

THE MEDICAL TREATMENT OF APPENDICITIS.[1]

BY A. J. HALL, M.D.,
OF WASHINGTON, D. C.

It is so generally admitted that appendicitis is a surgical disease that it is more than likely my suggestion that its treatment has a therapeutic aspect will meet a prompt negative. However, so many cases recover without surgical interference that it seems to me therapeutics have not received the credit to which they are clearly entitled.

A review of six papers advocating medical treatment,[1-6] which have come to hand during the last year, has failed to reveal anything satisfactory in the way of statistics, the number of cases not being given and the mortality being roughly estimated at something between five per cent. and ten per cent., but the writers express themselves as entirely satisfied with their results. In these papers I failed to discover a method or

1 Read at the Annual Meeting of the American Therapeutic Society, New York, June 2, 1904.

treatment that was generally applicable; some writers making no mention of local applications; some using them hot and others using them cold; some used opium and anodynes and others advised against their use or made no mention of them; some fed by mouth, others by enema only;[8] some used cathartics, and others did not. No mention is made of medication with a view of directly influencing the diseased process, "general principles" and the "expectant plan" being phrases used where, in my opinion, the details which carry a case to a successful issue should be minutely explained. The writers usually admitted that under certain circumstances they would advise operative interference.

The appearance of these papers shows that there is a strong sentiment in favor of medical treatment, as of course only a small percentage of its advocates are enthusiastic enough to express their sentiments in print. In the matter of statistics, I am as much at fault as the writers referred to, as I have kept no case records and have no figures to offer; still, the impression made upon my mind by a number of cases in which there has been no surgical interference and no death, is, that appendicitis may be treated medically with a fair prospect of as good results as those obtained by the surgeon, the proportion of recoveries being so large that the physician can safely count upon successfuly carrying his patient through the first and second acute attacks, and that the proposition to operate should be considered in the interval between the second and prospective third attacks.

Without touching upon the very interesting subjects of etiology, pathology, symptomatology and diagnosis, any one of which affords ample material for a lengthy paper and interesting discussion, I will show the actual condition the physician is called upon to treat by quoting a few figures from a paper by a surgeon. Dr. Winslow[7] operated upon three cases on the second day and found two of them to be pus cases and one clean. Of 14 cases operated upon during the first seven days, ten were pus cases and four were clean. Between the eighth and thirteenth days, three cases were operated upon without finding pus. On the fourteenth and twenty-first days, five cases were operated, pus being found in four. Of these cases, 39.5 per cent. were clean and 60.75 purulent. Of the 12 cases operated during the first five days 75 per cent. were purulent. Supposing that these figures will hold good in the average run of appendicitis cases, then it may be said that the class of cases which have been treated medically with satisfactory results includes every variety, from the endo-appendicitis, or mild catarrhal form, to the para-appendicitis, or severest form, in which the inflammatory process has involved all the tissues of the appendix and extended to surrounding structures with the formation of abscess. This statement is borne out by the experience of Dr. Lewis,[8] who reports eight cases, each of which developed abscess, the abscesses discharging through the bowel, and all recovering under medical treatment.

Having diagnosed acute appendicitis, my method of medical treatment is as follows: The patient must be placed at rest in bed, and this rest made as absolute as possible, an essential element in this regard being the installation of a nurse who can have a good influence over the patient, relieving him, if possible, of all care and certainly of all muscular effort on his own behalf. The abdominal muscles may be relaxed by flexing the thighs and supporting the knees by pillows. The vomiting and peristalsis of the bowel may be reduced to the minimum by withholding all food for the first twelve or twenty-four hours and the omission of anything in the form of cathartics or purgatives. A copious enema of soapy water or sweet oil should be used every four hours and a hot flax-seed meal poultice must be maintained over the whole of the abdomen, replacing it every two or three hours, night and day, until the temperature is normal. This application reduces the pain to such an extent that the use of anodynes internally or hypodermically can be avoided, especially if we convince the patient that the pain will probably subside in a day, and that medication might obscure symptoms that would be of vital interest during the next few hours. The amount of relief afforded by the poultices in the matter of nausea, vomiting, pain and fever is the index of the success or failure of the treatment.

In acute appendicitis fever is always present and the pulse rate increased; and the most important guides of the progress of the case are the temperature and pulse rate, a steadily increasing pulse rate being a sign of ill omen, while a diminishing rate gives assurance of a good prognosis.[9] The only counter indication for the use of enema, or at least one calling for great care in its use, is the involvement of the lower bowel or rectum in the inflammatory process, which occurs when the appendix is deeply seated in the pelvis, and doubt upon this point should be cleared up by a digital examination of the rectum. The rest and quiet of the bowel can be further promoted by the avoidance of repeated palpations, or even percussions, in an effort to demonstrate a swollen appendix or its surrounding abscess wall, the existence of which may be taken for granted, and the size need have no bearing on the case.

When the vomiting subsides the patient may be fed liberally by the mouth with milk, water and soups. The larger the amount of liquids consumed the better, as they not only nourish the patient, but by means of the diuresis produced render material aid in the elimination of toxic materials. Creosote, minim one, in two drams of lime water, may be administered every two or three hours, and arsenite of copper, grain $^1/_{100}$ every three hours. The creosote is eliminated, in part at least, by the kidneys, and must therefore, while in solution in the blood, be brought into most intimate contact with the inflamed area, and does, I believe, exert a salutory effect upon the inflammatory process and the toxic elements generated thereby. The arsenite of copper I employ as an intestinal antiseptic, and I am convinced that it

prevents or diminishes tympanitis and the tendency to vomiting, and has a marked anodyne effect. If the vomiting does not subside, and should it become stercoraceous, occlusion or paralysis of the bowel is indicated, and operation is the only hope of relief.

Between the twelfth hour and the end of the second day symptoms will usually begin to mitigate, the pain, temperature, and pulse rate all gradually subsiding, the patient passing on to uninterrupted convalescence, the case terminating in complete recovery in from seven days to three weeks. On the other hand, if the pain should suddenly disappear, the temperature drop to normal or below, the tumor diminish in size, the abdomen become tympanitic, the pulse rate remain high or increase in frequency, and symptoms of shock develop, it may be inferred that the abscess has ruptured; and if it has not discharged into the bowel the symptoms may be expected to recur with increased severity in a few hours, and another stage, acute diffuse septic peritonitis, is reached, where operation is indicated, though under very unfavorable circumstances. The condition is so hopeless in fact that some surgeons have refused to operate, partly because it may be attended by one or more secondary abscesses, yet, even this condition has been successfully tided over by reinaugurating the treatment at first outlined, using stimulants liberally and large amounts of normal salt solution hypodermically.

To recapitulate: An efficient medical treatment of acute appendicitis is as follows: Rest in bed, hot poultices to the abdomen, a liquid diet, chiefly composed of milk, four to six enemas a day, internally the arsenite of copper and creosote. Purgatives and opiates are not to be used.

Conclusions—The tendency of appendicitis is toward recovery. All acute cases should be treated medicinally until, after mature deliberation, it is shown that operation offers a better prospect for recovery. In recurrent cases operation should be advised during the interval after recovery from the second attack.

The Non-transmission of Acquired Immunity to Poisons.—In an experimental investigation of the phenomena of immunity to abrin poisoning, to which it is possible to adapt fowl by means of intraperitoneal injections of this poisonous proteid obtained from the seeds of wild licorice, A. LUSTIG (*Arch. Ital. de Biol.*, May 31, 1904), found that this immunity acquired by either parent can not be transmitted to the offspring. He concludes therefore, that there is no such thing as the hereditary transmission of immunity, and that the result obtained by Ehrlich can be interpreted only in that immunizing substances may pass from mother to fetus by way of the placenta.

THE CORRECTION OF ABNORMAL CONDITIONS OF THE BLOOD RELATIVE TO SURGICAL OPERATIONS[1]

BY S. C. EMLEY, A.B., M.D.,
OF WICHITA, KAN.;
LATE PATHOLOGIST AUGUSTANA HOSPITAL, CHICAGO, ILL.

FREQUENTLY the surgeon is called upon to operate on patients who, when they first present themselves, are in no condition to stand an operation on account of deficient quantity of blood or the poorness of its quality. On the other hand, it is desirable that the patient regain his normal condition as soon as possible after operation, whether the abnormal condition of blood is due to the operation or not.

The ideal remedy is that which will restore the normal condition of the blood in the shortest time with the least disturbance to the rest of the body, the digestive system particularly. Less necessary are palatability and cost of the remedy. To determine which of several preparations best fulfilled the above conditions was the purpose of this investigation.

All of the preparations used being recognized as good, Dr. A. J. Ochsner gave me permission to prescribe them as I saw fit to certain of his patients in Augustana Hospital. Only those cases were selected whose appearance indicated the need of a hematinic. As often as possible similar cases were paired off, one patient being given one preparation and the other patient another, and the results compared. The cases were paired according to pathological condition, age, sex, general condition and the condition of the blood as to hemoglobin and erythrocytes at the beginning of treatment. The preparations used were malt with iron and manganese; malt with iron, quinine and strychnine; Blaud's pills and the preparation known as pepto-mangan-Gude.

After watching the effect of the medication on the patients, and observing the records, it is seen that Blaud's pills acted quickly, but constipated; the malt combinations caused nausea in a few patients, and the malt, manganese and iron combination constipation in nearly all. The pepto-mangan, given in milk, was agreeable to take, and in no case did it cause nausea or constipation. While in two cases the Blaud's pills acted more quickly than pepto-mangan in two similar cases, on the whole the latter gave better and quicker results than any of the others, and at the same time caused no digestive disturbances in any of the cases.

Although the investigation was undertaken for the purpose of finding the best hematinic for surgical cases, it was tried in one case of chlorosis and in several obscure medical cases.

The following table shows the results obtained in all those cases where Gude's preparation was given. One to four drams were given in milk to each case, three times a day. The hemoglobin

1 Received for publication June 2, 1904.

was estimated with Von Fleischel's hemometer and the erythrocyte count made with the Thoma-Zeiss apparatus. The first blood count was made previous to operation in all surgical cases, and the last a short time before the patient's discharge from the hospital. The second count was never made immediately after the operation because of the temporary derangement due to the anesthetic and the loss of blood:

In the nineteen cases tabulated there is an average increase of 800,000 erythrocytes and of 14.5 per cent. hemoglobin. This improvement was during forty days on an average. The usual time a patient stays in the hospital is twenty-one days when the case is of ordinary severity from a surgical standpoint. Such cases were placed on tonic treatment and showed rapid improvement, but of such cases only one (Case 16) is noted because it might be urged they would improve equally fast with or without a tonic.

It is seen from the above table that even in the cachexia of carcinoma there is a temporary improvement, which shows that in the use of this tonic we are dealing with a powerful hematinic. In Case 17 there was no improvement, the patient dying shortly after the last count. At the autopsy I found a pyogenic abscess in the liver as large as an orange and about 200 c.c. of pus below the right kidney, which explained the retrogression. In all of the other operated cases the improvement was steady and marked, especially in uterine diseases accompanied by loss of blood. In the case of chlorosis (Number 9) the improvement was remarkable, the patient being discharged cured in a little over a month, at which time all the symptoms had disappeared.

[1] Incurable.

ADDISON'S DISEASE, WITH AND WITHOUT ADRENAL TUBERCULOSIS.[1]

BY CHARLES F. WITHINGTON, M.D.,
OF BOSTON, MASS.;
VISITING PHYSICIAN, BOSTON CITY HOSPITAL, INSTRUCTOR IN CLINICAL MEDICINE, HARVARD MEDICAL SCHOOL.

I AM well aware of the strong protest which the above title would have called forth from certain prominent medical writers of two decades ago, and which may still be made by some writers of our own time who, like their predecessors, hold to the so-called "unity" of this disease. This belief rejects from the category of Addison's disease all cases in which the pathological lesion is aught else but a tuberculosis of the adrenal glands. For example, Greenhow,[1] in his admirable Croonian lectures of 1895, in which he studies 330 cases thus diagnosticated, accepts only 103 as perfectly typical, because in only that number were there found tuberculosis of the adrenals without any organic disease of any sort outside of these glands. To these he adds, with reservation, 80 more, 16 as being probably incompletely reported in certain details, and 664 others which, while showing the full clinical picture of Addison's disease, did have lesions outside of the tuberculosis of the adrenals, which lesions gave rise, in his opinion, in many cases to symptoms of their own, and in a few instances modified or obscured some of the usual symptoms of Addison's disease. Two of the groups which Greenhow rejected were thrown out because of the lack of complete conformity to the Addison complex, in that in one case there was no disease of the adrenals, and in the other group a disease non-tuberculous was found. Certainly the rejection of cases of Addison's complex arising from cancer of the adrenals, because the disease was not tuberculous, is hardly to be taken as proof that Addison's disease can never arise except from adrenal tuberculosis.

Wilks was also an adherent of this view of the unity of Addison's disease, though it is to be remembered that Addison[2] himself was of the opinion that not only one fibrocaseous lesion but others, such as cancer, might produce the symptoms.

[1] Read at the Association of American Physicians, Washington D. C., May 11, 1904.

Dr. Dyce Duckworth[3] expresses his general adherence to what he calls the doctrine of the Guy's Hospital school, that the lesion of this disease is a specific and tuberculous one, and says: "It appears probable that continued research into the nature of the specific deposit and changes met with in Addison's disease of the adrenals will render it certain that these changes are always of a tuberculous nature." Yet, despite this dogmatic statement, he admits some of the difficulties in the way of the simple unity of the disease, and more than hints that a broader pathogenesis may have to be sought for it.

Now, the term Addison's disease is to be considered to indicate a clinical syndrome, consisting of bronzed skin, constitutional disturbance, gastro-intestinal irritation, and usually progressive weakness. The bronzing is the most conspicuous feature, but not the solely essential one. It has been said to be an indirect rather than a direct adrenal symptom. It may even be absent, though, if so, the disease can hardly be diagnosticated ante mortem. It has been said that the bronzing bears somewhat the same relation to the rest of the disease that the eruption of scarlet fever does to the other manifestations of that disease. Both the bronzing and the rash may be absent, though very exceptionally. But the eruption alone is not scarlet fever, nor is the bronzing Addison's disease. Each, plus its own allied symptom-group, warrants the respective diagnosis.

With this very proper precaution as to diagnosis, Addison's complex is certainly observed in more than one sort of pathological process. Admittedly the great majority of cases are found in tuberculosis of the adrenals.

But Lewin's[4] well-known figures are to be borne in mind. Among 281 cases he found: typical cases of Addison's disease with sound adrenals, 20 per cent.; typical cases of Addison's disease with diseased adrenals, 80 per cent.; disease of adrenals without bronzing, 28 per cent.; disease of adrenals with bronzing, 72 per cent.

Let us, then, in the present study adopt the following classification:

I. Cases with skin bronzing: (*a*) Adrenal tuberculosis, the commonest type of Addison's disease; (*b*) Adrenal disease, non-tuberculous: Atrophy, chronic interstitial inflammation, cancer, occlusion of adrenal vein, hemorrhages; (*c*) No adrenal disease: (1) With disease of the semilunar ganglion; (2) without disease of the semilunar ganglion; (3) pigmentation, usually without other symptoms of Addison's disease.

II. Cases without skin bronzing: (*a*) Adrenal tuberculosis: (1) With tuberculosis elsewhere: (2) without tuberculosis elsewhere; (*b*) Adrenal disease, non-tuberculous: (1) Cancer; (2) tumors; (3) necrosis, etc.

The cases of Addison's disease which I have to report, and which are limited to such as have post-mortem evidence to sustain them, fall under the first two of the above categories. Three of them correspond to the commonest type, showing well-marked adrenal tuberculosis, with small amount of tuberculosis elsewhere in the body. The fourth case is of greater interest, as being clearly one in which there was absolutely no tuberculosis of the adrenals, but a simple and extreme atrophy.

Case I.—Mr. H. S., aged forty years, seen in November, 1897, with Dr. Clement, of Roxbury, to whose courtesy I am indebted for the history. Patient had always enjoyed good health. Several years ago had a severe injury to the foot, followed by inflammation and suppuration through the sole. Always had a dark complexion, but for a year past had been growing darker, as observed by his friends. Dr. Clement was called to see him the last of February, 1897, at which time he complained of great weakness, loss of appetite, nausea, and vomiting. About a year before this he began to lose flesh and strength; at times was faint and nauseated, particularly on moving or rising. During the summer he was quite miserable, but went away and improved, gaining ten pounds in weight. After returning in the autumn he said he "felt quite well." Four weeks after that he began to fail rapidly, though he continued to work up to three weeks of his death. Never had a cough. Skin pigmentation began about this time. The skin was a quite uniform mahogany color over most of the body, and there were dark patches on the mucous membrane of the mouth. The skin was that of a dark mulatto, the hands and face being the darkest part. No mottling of the skin, but a uniformly deep mahogany color. His emaciation was not extreme. He lived about a week after first calling medical aid; the nausea and vomiting continuing until exhaustion caused his death. His mind was clear to the last, long after his pulse at the wrist had ceased. At autopsy both pleural cavities were obliterated by adhesions with a few small, hardened, tuberculous areas at the apex of lung. There were no other evidences of tuberculous disease than in the lung apices and the adrenal glands. These were removed with the kidneys, and Dr. W. T. Councilman kindly examined them, and reported as follows: "Two kidneys and a portion of apex of lung brought for examination. At the apex of the lung there are circumscribed, dark-pigmented radiating cicatricial areas, and about these various small, miliary, caseous foci. Both kidneys and adrenals present. The right adrenal is firmly adherent to liver. The gland enlarged; on section showed a central area of caseation with partial puriform softening, and around this dense cicatricial tissue in which miliary foci can be seen. The fat is apparently hyperemic and extends into the tissue. None of the adrenal tissue, as such, can be made out. In the kidney immediately bordering this the cortex is white, swollen, somewhat softened, and in the cortex at one point there is an obvious extension of the process. At this place no separation can be seen between the adrenal tissue and that of the kidney. Elsewhere there is no lesion in the kidney. The left adrenal gland easily separated from the kidney. It is reduced to the size of a filbert, and in this there are caseous areas and cicatricial masses. There is no

evidence in either adrenal of any remains of the glandular structure."

Case II.—A. A., male, single, aged thirty-five years, Syrian, pedler, entered Boston City Hospital February 20, 1903. History of some illness two years ago, with cough, vomiting, and fever. Says he made complete recovery. Worked until three weeks ago, then chilly, slight cough, headache, backache (which last he ascribed to carrying heavy bundles). Patient is undersized, not well developed. Temperature, 102° F.; pulse, 104; respirations, 28. Skin throughout the body is very swarthy, evenly. This color was supposed to be a racial peculiarity. The patient spoke little English and no friend visited him. Nothing could be learned as to any recent increase of pigmentation. Pupils were equal and reacted well. No hemiplegia; tongue protruded straight. Respiration over both apices in front is harsh, without râles. Over both bases behind equally subdued, without râles. The examination was otherwise negative, save for a markedly scaphoid abdomen. Kernig's sign present; no Babinski. Patellar reflexes equal and present. Attempted extension of left leg causes pain in lower lumbar region. Leucocytes, 16,400. The following day there was only slight patellar reflex; some rigidity of lumbar muscles.

February 23 there was great restlessness, with some vomiting. Lumbar puncture was done, and 50 c.c of slightly flocculent fluid withdrawn, some tension within the canal being shown. This fluid proved to be sterile.

The patient became drowsy; there was considerable retraction of the head with flexion of the lower extremities, and he died on February 24, two days after admission.

The autopsy showed adherence of right pleura at base and both apices. Few small, old tubercles at both apices. No tubercles were found in brain or meninges. There was chronic fibrous thickening around the veins of the sulci. Vessels of the base were normal. The lateral ventricles and the fourth ventricle contained an increased amount of clear, straw-colored fluid. The pia, especially over the cortex, contained many scattered pigment spots, which were thought to be due to diffused modified hemoglobin. There was no evidence of intracellular pigment beyond a moderate number of the pigment and detritus-containing phagocytes so frequent in this region. A small ischiorectal abscess was present.

The left adrenal was a large, tuberculous mass, 5 cm. by 2 cm., varying from calcareous to puriform in constitution. Right, similar but not so large; size, 2 cm. by 3 cm. The diagnosis of Addison's disease was not made in this case during life, but the constitutional symptoms and swarthy color of the skin, taken in connection with the findings of the autopsy, warrant the diagnosis.

The absence of demonstrable tubercles in the meninges was, in view of the clinical symptoms and of the hydrocephalus, a surprise. The presence of considerable pigmentation on the pia is interesting in view of the statement of Duckworth, that it is doubtful if pigment is ever found deposited in any internal organs in Addison's disease, though he quotes one observation by Carrington of pigment in the pia mater.

Case III.—Autopsy by Dr. F. B. Mallory, who kindly gives me notes of the case. Patient, a woman, aged thirty-three years, well built, fairly well nourished. The clinical symptoms had consisted of progressive weakness; the duration about a year. The attention of the physician had apparently not been attracted to the adrenals. Hair rather light in color; skin dark in color, like that of a brunette. Areola of nipples dark. Conjunctivas slightly pigmented. Bronzing general. Gall-bladder and ducts normal. Bile flowed easily into duodenum. Pancreas, stomach, and intestines apparently normal. Adrenals each contain a caseous mass less than 1 cm. in diameter. Besides this, small areas of caseation and calcification. Thin, small masses of fibrous tissue. Both glands much diminished in size. No trace of adrenal tissue. Small, flattened, caseous nodules in semilunar ganglion. Several adjoining glands enlarged.

Anatomical Diagnosis.—Chronic tuberculosis of adrenal glands, semilunar ganglion, and of adjoining lymph nodes.

Case IV.—Adrenal atrophy with Addison's disease. I. E. P., female, aged thirty-five years, born in Germany; housework. Had measles, smallpox, chicken-pox, and scarlet fever when young. Rheumatism at eighteen years. Has been well since. Patient states that pigmentation of skin has come in past year. Since last summer has been run down. Complains of pain in feet and ankles, extending up to knees. Feet have been swollen at times. At times has had dull pain in her hands. Gets out of breath easily. Gets up once at night to pass water. Eyesight not very good, especially in right eye. No cough. Appetite fair. Digestion is good. Bowels constipated. Chief complaint is weakness.

Physical Examination.—Well developed; cachexia; pale. Face covered with irregular pigmented areas, varying in size from 1 mm. to 5 cm. in diameter, occupying old smallpox scars.

Abdomen.—Not distended. Considerable voluntary spasm, so that palpation is difficult. No masses felt. Separation of recti.

Skin.—Irregular pigmented areas scattered over entire cutaneous surfaces. Pigmentation most marked in axillas, groins, abdomen, and back.

March 2.—Liver edge just felt in full respiration. Movable kidney on right felt with great distinctness. Chest and heart negative. Marked diffuse brownish pigmentation back of neck, axilla-scapular regions. In lumbar region it is more markedly macular. Marked pigmentation at folds of knee-joints. Face is now marked with pigment in each cicatrix, which patient says was not present one year ago. Tuberculin test negative, but not to be considered, owing to unreliability of tuberculin used.

March 5.—Since admission has shown marked

general weakness. Complains of general pains in shoulders and extremities. Nauseated and vomited on several occasions. Yesterday afternoon up in a chair for short time. No apparent change in condition noticed afterward. About 11 P.M. patient found in a state of collapse. Heart action slow and weak. Pulse (radial) barely felt. Extremities cold. Marked pallor; very much excited. Emotional, groaning and crying out persistently. Cries due to fright from weakness—not from pain. Failed to respond to stimulation, and died at 4:05 A.M.

Autopsy, thirty-two hours post mortem, by Drs. F. B. Mallory and R. L. Thompson. Body length 152 cm. Body of a slender, gracefully-built woman. Lividity of dependent parts. Pupils 6 mm., equal. Rigor mortis present. No edema. Over the face and neck are closely set brown macules, mostly discrete, 0.5 cm. to 1.5 cm. in diameter. There is a slight brownish tint to the skin over the abdomen and about the axillæ.

Peritoneal Cavity.—Very little omentum or retroperitoneal fat. Serosa pale in color, normal in appearance. Right kidney lies directly under gall-bladder, and is freely movable. Mesenteric lymph nodes slightly enlarged, grayish-red in color. Appendix 6 cm. long; retrocecal; has a mesentary to tip. Diaphragm extends to fourth space on left, fourth rib on right.

Pleural Cavity.—There are a few fibrinous adhesions about the right apex. Remainder of cavity normal.

Lungs.—Voluminous; show the usual carbon tracery. Posterior portions somewhat congested. At the right apex pleura is thickened, and there is an old fibrous nodule, 3 cm. in diameter, the center of which is filled with cheesy material surrounded by thick fibrous wall. The remainder of the lungs is dark red. On section considerable blood-stained fluid exudes on pressure. Bronchi contains sticky, mucoid material.

Kidneys.—Weight, 230 grams. Cortex, 6 mm. Capsule strips readily, leaving smooth surface marked with stellate veins. On section kidney is pinkish-red in color. Cortex and pyramids show normal differentiation. Glomeruli seen as fine, glistening dots. Fresh section shows large amount of fat in small and medium-sized droplets in basement membrane of tubules.

Adrenals.—Very small in size, both together weighing less than 5 grams. Medulla practically not to be made out. Right with considerable connective tissue weighs 2 grams; left, 2.25 grams.

Microscopical Examinations of Adrenals.—The lesions consist in atrophy of the gland with destruction of the adrenal cells, marked fibrous change, and areas of lymphoid and plasma-cell infiltration. A greater part of the atrophied gland, both cortex and medulla, is replaced by fibrous tissue. Other portions show narrow areas, in which the remnants of gland tissue, detached from the basement membrane, and in various degrees of degeneration. These detached cells lie in connective-tissue stroma, which is infiltrated with lymphoid and plasma cells. The lymphoid and plasma cells sometimes form definite focal areas in which may appear an occasional adrenal cell. Bloodvessels are injected, walls not thickened. No evidence of tuberculosis could be found in either adrenal.

ADRENAL ATROPHY.

The case last reported belongs to a category, not large, of simple atrophy of the adrenals. As such cases are likely to be challenged by a believer in the "unity" of the diseases I append a brief report of a few other cases.

Barlow[5] reports a case of a woman, aged forty-two years, in whom both the adrenals together weighed less than 0.5 drachm. There was also gumma of the left kidney. There was brown pigmentation, most marked on the neck, behind and in both axillas, around the nipples, flanks, and groins, also in the mucous membrane of the mouth. The inner side of the knees and the dorsum of each foot showed an irregular mottling of darker pigmentation. The abdomen showed a dark line from pubes to ensiform. She had had a recent pregnancy, terminated by delivery of a stillborn child, but the pigmentation had antedated the pregnancy and developed rapidly since its close. There was fever (99° to 102° F.), vomiting, and death.

F. Roloff[6] reports a case in which there was characteristic Addison's disease in a man, aged twenty-two years, in whom this pigmentation had begun thirteen years before, but who had felt practically well till five days before his death. The post mortem revealed only an extreme atrophy of both adrenals without the slightest tuberculosis. There was also no lesion of the similunar ganglion.

Philips[7] reports a very similar case, where pigmentation had begun fourteen years before death, but for seven years had been unaccompanied by any symptoms. The adrenals were atrophied, not tuberculous.

Both these writers have apparently independently made a collection of all similar cases from the literature, which together amount to fourteen. In all of these tuberculosis was absent from the adrenals and in only three was there tuberculosis of any part of the body; in two cases no adrenals were found. To these 14 cases of adrenal atrophy with Addison's disease the one above reported adds a fifteenth.

Rolleston[8] calls attention to the fact that the adrenals may diminish in size in old age, but in his 1,050 post mortems found them small in only six patients under forty-five years of age. These showed no signs of Addison's disease. But he adds that he has never seen the extreme atrophy described in some cases of Addison's disease in which the organs were reduced to the size of peas.

CANCER OF ADRENALS.

In his original paper Addison included three cases of secondary carcinoma of the adrenals, and one in which a secondary carcinomatous nodule

blocked the adrenal vein and caused hemorrhage into the capsules. These he later wished to remove from the category, and ascribed their share in the production of the symptoms to the proximity of the lesions to the sympathetic.

Greenhow rejects nine cases of Addison's disease with adrenal cancer; six as not being Addison's disease and three as (while undoubtedly Addison's disease) *not* cancer, but tuberculosis of the adrenals. One of these reported by Gage, of Worcester, occurred in a woman whose breast he had removed for scirrhus two years before without recurrence. There were pigmentation and constitutional symptoms for six months. The adrenals were joined together by a thickened mass of enlarged and diseased lymphatic glands. This case is rejected on account of the lack of microscopical examination, but as many of the cases were before the days of the microscope and this test was not insisted on when the disease appeared to be tuberculous, the justice of this ground of exclusion does not appear.

Other writers like Rolleston do admit cancer as a possible cause of Addison's disease, though it is apparently rare and both glands may be destroyed by cancer without the production of symptoms. But the same is true of tuberculosis.

Hemorrhages into the substance of the adrenals have been noted as connected with Addison's disease, not only in the case reported by Addison himself and above referred to, but also by Virchow as seen in some rapidly progressing cases of Addison's disease.

ADDISON'S DISEASE, INCLUDING BRONZING AND CONSTITUTIONAL SYMPTOMS, WITHOUT DISEASE OF THE ADRENALS.

Lewin in his classic monographs finds, among a total of 281 cases, 68 patients with the symptom-complex, but without lesion of the adrenals, being something like 20 per cent. of the cases. Shall these be rejected because they do not conform pathologically to the more common type? Lewin sees no reason to reject them on this ground, although other authors are inclined to do so in similar cases.

Let us for a moment consider, as fairly illustrative of this class, the case of Merkel.[9] A man aged forty-six years, ill-nourished, shows weakness, decrepitude, anorexia, and a strikingly bronzed skin, including both the covered and uncovered parts of the body. Although he has always been dark, the pigmentation has greatly increased of late. He has dark spots on the buccal mucous membrane. Fever, vomiting, abdominal distress, diarrhea, increasing weakness, delirium, death. The ante-mortem diagnosis was Addison's disease, of which the buccal pigmentation (pointed out by Niemeyer as pathognomonic) seemed to the author the final and conclusive symptom. Post-mortem there was moderate internal hydrocephalus, with granular ependyma, miliary tuberculosis of the peritoneum and of an enlarged spleen, perisplenitis, perihepatitis, scant miliary tuberculosis of the liver, and fatty degeneration. Normal adrenals. Some enlarged retroperitoneal glands, but no caseous focus. The skin pigment was like that in Addison's disease, granular and distributed in the deep cells of the rete Malpighii. Yet Merkel, on the strength of the autopsy, eliminates this case from the category of Addison's disease, saying merely that the case destroyed for him the pathognomonic significance of pigmentation of the mucous membranes in connection with the rest of the Addison complex.

Another case instructive in this connection is that of Richon.[10] A girl of ten years, whose father died of phthisis and whose three brothers and sisters had died young, had complained for two months of weakness and anorexia, was depressed and always sitting or lying down. There was a darkening of the skin on the face, brow, commissure of the lips, trunk, back, glands, and buttocks. The backs of the hands were especially dark, chocolate colored; some darkening of the buccal mucous membrane. Consolidation of both apices. The injection of adrenal gland caused restlessness and vomiting, and was discontinued. She began to improve after three weeks and left the hospital much better. Returning after an absence of three and a half months, the pigment had gone from the face and was less on the rest of the body. In the middle of a month's stay in the hospital the pigmentation began to return. She again left the hospital, was taken with abdominal pain, vomiting, and cough. She was in bed for three months with vomiting and diarrhea. At the end of that time she entered the hospital again with no vomiting, but with increase in pigmentation and prostration, which in two months proved fatal.

The post mortem showed no lesion of either adrenal, either tuberculous or otherwise. There was tuberculosis at the apex of each lung. In the lower 40 cm. of the ileum there were ulcers with perforation. The semilunar ganglion and the ganglia of the solar plexus and the sympathetic nerves were all normal. They were surrounded but not pressed upon by voluminous lymphatic glands. Richon also quotes a case of Brault and Perruchet like his own case, except that theirs, while showing no lesion of the adrenals, did have a small tuberculous mass adherent to and penetrating the semilunar ganglion.

1. An important case is that of Jurgens,[11] which was that of the full Addison complex in a patient with a big aneurism of the aorta, which caused compression of both splanchnics and so atrophy and loss of function of both the corresponding adrenals. On the strength of this and another case, the author claims that in every case of true Addison's disease there is a gray degeneration of the nerve fibers of the splanchnics. This may be either protopathic, when one finds simple atrophy of the adrenals without other inflammatory appearances in these or other organs, or (more commonly) deuteropathic, in consequence of primary disease of the adrenals or pancreas.

2. These changes of the sympathetic system of the spinal ganglia and even of the cord have been recorded by many observers, but, on the other hand, have been definitely excluded in a sufficient number of cases to show that they are not essential to the production of the symptoms in question. Neusser says that minor degrees of such degeneration are found in various cachexias like pulmonary tuberculosis, and hence are of no significance. Most writers agree with Mann[12] that the structural changes which are usually present in the adrenals may or may not be followed by secondary changes in the semilunar ganglion.

3. Let us not forget, as Jaccoud has said, that bronzing without progressive asthenia and without visceral disturbances is not Addison's disease. Thus we shall not be misled into accepting the large number of cases which are on record as "simulating" Addison's disease, chiefly by reason of extensive skin bronzing. Certain affections of the female genital apparatus produce such bronzing, varying in extent from the pigmentation of pregnancy through the common chloasma uterinum to the pigmentations connected with marked ovarian disease, like that reported by Neusser,[13] where there was marked cystic degeneration of both ovaries with much skin pigmentation, which disappeared after the removal of the ovaries. Other skin pigmentations, sometimes extensive, are observed in diseases where cachexia may heighten the resemblance to Addison's disease. Still they are generally bronzing *plus* cachexia, not bronzing *with* cachexia. Such phenomena have been reported in scurvy; in chronic tuberculosis, especially of the peritoneum; in cirrhosis, particularly in Hanot's hypertrophic cirrhosis with diabetes;[14] certain pancreatic affections, with and without diabetes; in old amyloid disease; in chronic splenic enlargement with and without chronic malarial poisoning; in pellagra; in "vagabond's" disease; inchronic rheumatoid arthritis; in exophthalmic goiter.

TUBERCULOUS AND OTHER LESIONS OF THE ADRENALS WITHOUT ADDISON'S DISEASE.

The records of the Boston City Hospital show the following cases of adrenal tuberculosis without bronzed skin:

Case V.—(I. Medical.) S. W., female, aged twenty-seven years, single; housework; rheumatism three years ago. Two weeks ago gave up work, tired out, weak, pain in right ankle; temperature, 102° F.; pain and tenderness of joints with fever continued. Nothing detected in the lungs. She died after six days. There was stenosis and insufficiency of mitral valve and an acute endocarditis involving mitral and aortic valves. Passive congestion of the lungs. Old tuberculosis of old apices with miliary tubercles about them. Both adrenals enlarged, in both firm, completely caseous areas, surrounded by some dense tissue, a small portion of gland substance remaining in each. No record in clinical or autopsy notes of bronzed skin.

Case VI.—May 26, 1902 (II. Medical). S. D., aged nineteen years, single; elevator boy. Malaria two or three times. Typhoid years ago. For three weeks "tired out," abdominal pain, diarrhea. Consolidation left base behind. Temperature, 102° to 103° F. Bowels continued distended, but patient rather more comfortable. After nearly two months temperature still up. Prolonged expiration and crackling râles throughout right chest; friction, right axilla; few dry râles, left chest. Abdominal examination negative. Tubercle bacilli present.

July 24.—Sharp pain in left side; friction rub.

July 28.—Intestinal hemorrhage; spasm right rectus muscle, tenderness right of and below umbilicus. Spasm and pain intense. Pulse 140; temperature normal.

These conditions, with increased abdominal distention continuing, he was transferred to the surgical side for operation, which was performed August 2. There was found intestinal tuberculosis, with perforation. Fistula persisted, and he died August 8.

At autopsy there was found chronic tuberculosis of right apex; tuberculosis of mesenteric lymph nodes with softening; peritonitis; disseminated tuberculosis of lungs, spleen, and liver; tuberculosis of adrenal and bile-duct. The left adrenal was enlarged, particularly in the middle portion. On section inner and outer edges of adrenal appear normal, but interposed between these two is a firm, yellowish-opaque mass, granular on section, sharply circumscribed, and roundly contoured, which occupies the middle portion of the adrenal. In this area no traces of adrenal structure can be made out. It is impossible to demonstrate gross continuity between this adrenal and a large tuberculous lymph node in its proximity. The right adrenal does not appear to have been affected. No skin pigmentation.

Case VII.—T. M. (II. Medical). This case, adult male, pathologically showed nothing but a general lymphomatosis, with persistence of thymus and of red marrow. There was no tuberculosis demonstrated except in the right adrenal, which was firmly attached to the right kidney in a fibrous capsule, looking something like an elongated node. On section the upper part shows characteristic pigmentation of adrenal, but lower two-thirds for a distance of 3 cm. shows on section an opaque, yellowish induration, which completely obscures adrenal structure. A node embraced in the same capsule with the adrenal shows similar yellowish center, which has advanced to a trace of caseation. No skin pigmentation present.

Other cases of extensive adrenal tuberculosis without Addison's symptoms are not wanting. For instance, Rolleston found in his 1,050 postmortems 18 cases where there was caseation in the adrenals (eleven unilateral and seven bilateral) without evidence of Addison's disease.

Lewin found 53 cases where the adrenals were tuberculous without skin bronzing.

Roloff relates a case of total bilateral tubercular inflammation of the adrenals, without bronzing.

That in such cases as the foregoing a certain amount of adrenal function is still possible, through the existence of "adrenal rests," or accessory adrenals, is entirely possible. These adrenal rests may be found not only in the loose connective tissue, but embedded in the kidney or liver. Rolleston found five of these of the size of grains of corn on one side in one case where the adrenal was caseated.

Of other adrenal lesions without skin bronzing the Boston City Hospital records afford several cases. For example, there are three of cancer, as follows:

One of the cases was found in a patient dead with pneumonia and gangrene of the middle and lower lobes. Carcinoma was not diagnosticated during life, but was found post mortem in the liver, with metastasis in the omentum, mesentery, pleural surface, retroperitoneal glands and left adrenal gland. There was a healed tuberculosis of the left lung, but no skin pigmentation.

The other adrenal carcinoma was in a patient dying with palpable tumor of the stomach, with carcinoma demonstrated post mortem in the stomach, and with metastasis in the liver, lymph glands, rectum, and adrenal. No pigmentation.

In another case where the surgical diagnosis was intestinal obstruction, there was carcinoma of the cervix, with extensive metastasis, including the adrenals. No pigmentation.

There were two cases of atrophy—one in a patient dead of operation for ablation of the Gasserian ganglion for facial neuralgia. Pancreas and adrenals were all atrophied. No skin symptoms.

A similar atrophy of both adrenals and pancreas was found in a patient dead of organic disease of the heart, with dyspnea, edema, etc., but without skin pigmentation.

Four cases classified as "adrenal tumors" were apparently all of the same structure as the gland itself. One was a small tumor found in a man with fractured rib and lacerated liver. A second was in a man dead with chronic and acute pulmonary tuberculosis. The autopsy showed tuberculosis to exist also in the intestine, the peritoneum, and there was hyperplasia of the bronchial lymph nodes. Slight chronic peritonitis. The adrenals were normal in size. In the right one was a small nodule, size of a pea, in the substance of the gland, yellowish white, paler than the cortex to which it is connected, homogeneous, contour sharply marked. The left adrenal has a small cyst (5 mm.), irregular contour, and containing a small amount of brownish fluid material. Microscopically this shows cells like the cortex. Despite the extensive tuberculosis elsewhere, these tumors of both adrenals do not appear to have been of that character. The patient had presented marked cyanosis, but no skin pigmentation.

A third tumor was found in the left adrenal, having the dimensions of 2x1.5x1.2 cm. It was composed of yellowish tissue like the cortex. The right was normal. The patient had died "uremic," with amyloid kidney, aneurism of the aorta, and obliteration of the pulmonary artery. No skin pigmentation.

A fourth tumor was larger, occupying the right adrenal gland, which measured 6x5x3 cm. It was yellow and firm, size of a walnut, yellowish-gray, capsulated. Does not thread out. Blood content low. The patient died of chronic bronchitis. No skin pigmentation.

A case of necrosis of the left adrenal was found in a patient with pancreatitis, and is interesting chiefly from its pathological features other than those connected with the adrenals.

The patient, a woman aged forty-nine years, had acute abdominal symptoms, with a somewhat vague tumor in the site of the left kidney, which it was thought might be a pyonephrosis. Operation disclosed a brownish-black, soft, pliable mass, the size of a small orange, posterior, inferior, and lateral to the left kidney. The kidney was normal in size, color, and consistency, with no distention of the ureter. Fat-necrosis was found. The mass was removed and the cavity drained. The patient survived nearly ten days. The autopsy showed necrosis of the pancreas. Wirsung's duct patent. No stones. The gall-bladder ducts were empty and patent, the common duct dilated, and two mulberry stones smaller than cherries were found in the gall-bladder. The necrosis involved, besides the body and chief part of the head of the pancreas and the left perinephritic region, the left adrenal gland. No skin pigmentation.

That the tuberculous element in the adrenals, however frequently it is found, is not the sole and essential cause of the Addison complex is suggested by the experiments of Vecchi,[15] who injected tuberculous bacilli into the adrenal glands of rabbits. A tuberculosis of these glands was produced and there was extension of the process to the central nervous system, but no pigmentation either of the skin or mucous membranes was produced. He believes that these symptoms of Addison's disease are the result of two factors, adrenal insufficiency and an intoxication produced by the tuberculous process. But if the tuberculous process is, as we have shown, not an indispensable part of the disease, why should we not return to what was practically Addison's own theory, that any disease involving adrenal inadequacy may produce the symptoms, and that the part played by tuberculosis is simply that it happens to be the most frequent destructive lesion of the adrenal?

In 1885, Hadden[16] noticed the similarity of lesion in his case of Addison's complex from interstitial atrophy of the adrenal to the lesion existing in the thyroid in myxedema. Osler[17] pointed out more in detail the analogies between the loss of an internal secretion, as producing in the case of the thyroid myxedema, and in the case of the adrenals, Addison's complex. It is interesting in this connection to note that Rolleston in 1896 had suggested that in certain cases of adenomata or hyperplastic tumors of the adrenals the

symptoms might be due to altered structure and depraved secretion, just as Graves' disease depended upon similar processes in the enlarged thyroid. The far greater frequency of destructive and atrophic lesions of the adrenals in connection with symptoms of Addison's disease, however, makes the analogy of myxedema seem more reasonable than that of Graves' disease.

If this analogy prove true, should we not expect a therapeutic triumph similar to that over myxedema in those cases of Addison's disease where the adrenal inadequacy is not overshadowed by the strong toxic influence of extensive tuberculosis? Dubois,[18] taking the ground that the disease is a continuous auto-intoxication from the lack of an excretory action of the adrenals, says in confirmation of that view that the therapeutic use of capsular extracts by injection always produces toxic phenomena and hastens death. But of late we know that some definite observations have shown the opposite fact. Cases have been reported by Osler,[17] Shattuck,[19] Deeks,[20] Porpelow,[21] and others, showing marked improvement and in some cases cure of the disease, with disappearance of bronzing, under the administration of adrenal extract. There is certainly ground for encouragement in trying this remedy wherever advanced tuberculosis is not present.

Dr. M. Foster[22] points out that the cortex of the adrenals is derived from the masses of mesoblastic cells surrounding the great blood vessels, while the medulla is derived from and is a modification of the sympathetic ganglia. The former suggests important metabolic processes, some of which are connected with the history of pigments of the body at large. The latter suggests peculiar nervous connections. In some animals he adds that these two are wholly separate bodies. Probably the more important functions of the organ reside in the medulla, in which, for instance, Abel[23] finds that the blood-pressure-raising constituent is contained. The total extirpation of the adrenals is fatal.

Two views have been held as to the function of the adrenal glands—one expressed by Huisneau[24] that they attract to themselves certain toxic products originating from intestinal decomposition (*e. g.*, pyrocatechin) and from muscle action (*e. g.*, phosphoric and lactic acids), rendering them harmless and preparing them for excretion by the kidneys. The other, that there is a synthetic production of a substance essential to the maintenance by the sympathetic system of the nutrition and normal tone. The latter view is at present more favored by physiologists. But it is perhaps easiest to explain the symptoms of Addison's disease by assuming that both these functions are fulfilled by the adrenals. The failure of the first enplains the toxemia, the failure of the second the pigmentary and other nutritional changes.

MEDICAL PROGRESS.

SURGERY.

Excision of the Joint Capsule in a Gouty Toe.—The suggestion is made by RIEDEL (*Deut. med. Woch.*, August 25, 1904), that in suitable cases relief may be secured by removal of the urates and the joint capsule from the affected toe. He reports two cases in which this was done. In the first an operation was undertaken for what was believed to a suppurative arthritis, but on opening the joint, the latter was found to be filled up with urates. These were removed and the thickened joint capsule excised. The patient was relieved of his symptoms and remained free. He died twelve years later from some other disease. The second patient was a woman of seventy years, was operated under similar condition and also was free from further symptoms, until her death six years later from aortic stenosis. Riedel admits that the application of this procedure is limited to patients in whom the gouty process is thus localized and where it is general, the usual treatment must be followed. He advises leaving the wound open and packing it with iodoform gauze.

The Production by Surgical Means of New Anastomotic Channels for the Blood of the Portal Vein.—On the basis of later observations, S. TALMA (*Berl. klin. Woch.*, August 22, 1904) states that a negative answer must be returned to the question, does the operative deviation of the blood in the portal vein favorably influence hepatic cirrhosis. Another query, as to whether the attachment of the omentum to the abdominal wall diminishes the danger of hemorrhage from the overdistended veins of the abdominal viscera, may be answered by stating that the dilatation itself cannot be improved, but the danger of rupture is certainly lessened by the lowered blood pressure. Talma considers that omentopexy is indicated, however, whenever hematomesis is present as the result of hepatic cirrhosis. A case of portal thrombosis is reported, in which an operation was done, but without favorable results. The author is inclined to abandon the method, if it were not for the report of a case by Umber, in which numerous natural adhesions were found, which seemed to compensate for the presence of an obstructed portal vein that had evidently been in this condition for a number of years.

The Pathogenesis of Chronic Gastric Ulcer.—A satisfactory explanation of the chronic progressive ulcer has not yet been attained, according to W. G. MACCALLUM (*Am. Med.*, September 10, 1904) although a large number of investigations have been made. The opinion of most of these is that gastric ulcers may be produced by anything which produces a necrosis of the mucosa of the stomach and thus subjects it to the action of the gastric juice. While certain cases lend themselves to this explanation, there are others whose inception is obscure. The persistence of some of these ulcers offers the greatest difficulty of explanation and none of the theories advanced is satisfactory. MacCallum thinks that perhaps the great majority of ulcers do heal, and are recognized only later by the scars they leave, so that possibly Talma is right in saying that all ulcers tend to heal, but that frequently they last a long time because new ulceration occurs in the same spot.

Extirpation of Mucous Polypoids.—A polypus at times escapes the snare because it is too mobile, too low, too large or because its form is such that the wire loop slips over it. The best reason for this failure is that the snare, an excellent instrument for section is a poor one for prehension. Realizing this J. TOUBERT (*Arch. Inter. de Lary. d'Otol. et de Rhin.*, July, August, 1904) places the loop of the serrenœud over a long thin Kocher's forceps. The forceps with the noose around is manipulated with the right hand, the other being free to manage the speculum. The polypus is seized with the forceps which are self retaining, with them the polypus is held firmly, the noose is slipped along the forceps over the tumor, which by this combined manipulation is rendered easy. After section the polypus comes away, still held by the forceps.

Cicatricial Occlusion of the Nares.—This form of occlusion of the nares following variola is rather a frequent lesion. C. COMPAIRED (*Arch. Inter. de Lary. d'Otol. et de Rhin.*, July, August, 1904) states that while it may not be of great gravity in itself, it merits the close attention of the physician, because of the respiratory troubles it may produce, and especially because of the disfigurement that often results. If the latter take place, a plastic operation should be resorted to, which will depend mainly for success upon the postoperative treatment. The wound must be kept aseptic, and subsequent retractions prevented by the introduction of aseptic gause drains which later may be replaced by a sterile rubber or aluminum tube.

Ethyl-Bromide Anesthesia for Removal of Adenoids.—LAPAS (*Arch. Inter. de Lary. d'Otol. et de Rhin.*, July, August, 1904) recommends this narcosis as a means for the successful removal of adenoids and tonsils. Although it has the inconveniences of an early awaking of the patient and a contraction of the jaws, which at times is overcome only with greatest difficulty. Cases of death from its use have been reported. This anesthetic has three periods of action on the nervous system: (1) The cerebrum is anesthetized, the patient losing consciousness; (2) paralysis of the spinal cord and abolishment of reflex movements; (3) the bulb is affected, the heart with the respiration ceases and death results. From a surgical point of view the narcosis may be compared to a period of cerebral anesthesia with persistence of reflex movements, a period of complete anesthesia with paralysis of movements, a period of cerebral anesthesia with a return of movements. The first period lasts only a few seconds, the third, according to the deepness of the narcosis lasts from one to several minutes. It is these last two periods that are employed for the operation. The contents of a 20 gm. tube of ethyl-chloride is poured in a cone which is held firmly over the mouth and nose to prevent the access of air. Anesthesia accomplished, the head is held by an assistant and a mouth gag inserted. If contraction of the jaws is present it is overcome by putting a narrow tongue depressor between the jaws in the space just behind the molar teeth. It is absolutely necessary to have the patient held still when the reflex movements are present; in the case of a child this is easily done by an assistant, but with an adult it is necessary to have an operating chair in which the patient is bound. Although reflex movements return, the operation should be proceeded with, as the patient as yet has no sensation. If administered carefully there is no danger, the great advantage of this anesthetic being that immediately after the operation the patient is able to walk home.

Foreign Bodies in the Larynx.—F. MASSEI (*Arch. Inter. de Lary. d'Otol. et de Rhin.*, July, August, 1904) recommends for the removal of foreign bodies from the larynx, an instrument similar in construction and form to a small urethral sound, but the curve is more nearly at right angles than that of the sound. The distal end is blunt and bent near its extremity like a crochet hook. One should have four of these with the hooks turned in different directions. With one of these the author has drawn up an impacted chicken rib that resisted all attempts with a König forceps, even though a good grip was obtained.

The Spontaneous Cure of Cancer.—It has been claimed by a number of observers that the giant cells met with in carcinoma of the skin were to be considered as part of a curative process. R. BORMANN (*Deut. med. Woch.*, August 25, 1904) carefully examined over 250 cases on this point and although his observations agree with those of other investigators he considers that a wrong interpretation has been placed on their findings. He admits that the giant cells may form around foreign bodies, but that they do not surround living cells, particularly those of a proliferating new growth. If the latter occurred, a spontaneous cure might be spoken of, but there is no evidence that it takes place. In rodent ulcers, which may exist in a quiescent state for prolonged periods and where a process of this kind might be expected, nothing resembling it was found. The writer believes, moreover, that these giant cells are found in greater number in the rapidly growing forms of tumors, than in the slowly developing types of carcinoma. He disclaims that there is any such thing as phagocytic action, in which the giant cells play the main role, similar to that associated with the disposition of dead material in other parts of the organism.

Acute Pancreatitis with Recovery after Laparotomy.—Two cases, with a disseminated fatty necrosis in the abdomen, which have remained cured for over a year after operation, are reported by WIESINGER (*Deut. med. Woch.*, August 25, 1904). The prodromal symptoms in both cases comprised digestive disturbances, followed by severe epigastric pain, vomiting, absence of stools and flatus, alternating with periods of profuse diarrhea. The diagnosis was not made until the laparotomy disclosed the fatty necrosis scattered throughout the abdominal cavity. The author considers that this affords the most conclusive symptom, and where it is present, the blood-stained serum in the abdomen should be

evacuated, the bursa omentalis drained, but the viscera should be disturbed as little as possible. The operation should be done without a general anesthetic, if possible. In one of the patients, laparotomy was done a year afterward for another condition, and the areas of necrosis were found to have been fully healed.

PHYSIOLOGY.

The Protective Value of Proteids on Trypsin.—Arguing from recent researches, H. M. Vernon (*Jour. of Physiol.*, August 22, 1904), concludes that most, if not all, ferments are to some extent protected from the destructive action of acids or alkalies or high temperature by the presence of proteids. The evidence on the whole seems to indicate that such protection is exerted mainly by the proteid combining with the acid or alkaloid present, and so preventing it from reacting upon the ferment; but it might also be held to argue that some combination or interaction takes place between ferment and proteid. The researches of the author show that the former supposition is the correct one, although in certain cases a combination of ferment and proteid does occur.

Metabolism in Fasting and Feeding.—In a series of experiments performed on rats, E. S. Pembray and E. I. Spriggs (*Jour. of Physiol.*, August 22, 1904), find that during fasting the respiratory exchange quickly reaches a minimum, and then remains remarkably constant during the prolongation of the fast. The effect of food rich in carbohydrates upon the respiratory exchanges is well marked within an hour, and steadily increases during the next two or three hours. The increase in the output of carbon dioxide varied acording to the conditions from 14 to 97 per cent. of the minimal discharge during hunger; the increase in the absorption of oxygen was 9 to 35 per cent., but in three cases it fell below the minimal discharge during hunger. This decrease in the absorption of oxygen may be explained, as Zuntz and Lehman suggest, by the fact that carbohydrates yield more heat from their oxidation than do fat and proteid, when the consumption of oxygen is equal in the two cases, and thus the animal can satisfy its needs of energy by a smaller absorption of oxygen. On the other hand it might be due to diminished muscular exercise of the feeding. The increase in the discharge of CO_2 after a meal appears to be due to a general increase in the metabolic processes of the body, including the formation of fat, and not solely to the work of digestion. A fast preceding a meal serves as a marked stimulus to the assimilation of food.

The Spinal Respiratory Centers.—The researches of Rokitansky, Langendorff and Wertheimer, have revealed the presence of spinal respiratory oblongata. This fact is confirmed by A. Mosso (*Arch. Ital. de Biol.*, May 31, 1904) In experimenting on kittens the author found that on completely severing the cord just above the first cervical nerve, and by keeping the animal warm and by maintaining artificial respiration until the effects of the shock have passed off, at the end of forty minutes the cat takes six or seven respirations, each followed by four or five feebler ones. This form of restored breathing might be characterized as a periodic one, phases of repose alternating with phases of activity. The spinal respiratory centers are rapidly exhausted, and the breathing becomes shallower and shallower until it finally ceases. The renewal of artificial respiration restores spontaneous breathing which is more vigorous than before. The respiratory curve resembles that seen in asphyxia. It is probable that the respiratory cells in the spinal cord have the same function as those in the medulla oblongata, and react in the same way to asphyxia.

Carbon Dioxide in the Blood in Diabetic Coma.—An analysis of the quantity and presence of carbon dioxide in nervous blood and in alveolar air in cases of diabetes and diabetic coma, revealed to A. P. Beddard, M. S. Pembrey and E. I. Spriggs (*Jour. Physiol.*, August 22, 1904), that it is probable that the respiratory center is stimulated by other substances than carbon dioxide, and that in coma the hyperpnea, which is marked by the depth of the inspiration and expiration, reduces the volume of carbon dioxide in the nervous blood, for it has already been shown that the pressure of the alveolar carbon dioxide fall to 2.2 per cent. of an atmosphere. Lehman showed that weak acids stimulated the respiratory center, and Geppert and Zuntz, from an examination of the gases in arterial and venous blood, came to the conclusion that the hyperpnea produced by muscular exercise was due to some products of metabolism and not to an increase of carbon dioxide or a decrease of oxygen in the blood. During the treatment of patients suffering from diabetic coma by the injections of solutions of sodium bicarbonate the typical deep ventilation of the chest disappears. The author's observations do not support the view that the low proportion of carbon dioxide in the venous blood in diabetic coma is directly dependent on the reduced alkalinity and a reduced carrying power of the blood for that gas. They suggest that the hyperpnea is a cause and not an effect of the reduction of the carbon dioxide in the blood.

The Elasticity of Animal Tissues.—What is known as Hooke's law, namely, "that the power of any spring is in the same proportion with the tension therof," is found by J. B. Haycraft (*Jour. of Physiol.*, August 22, 1904), to be applicable to all the simple tissues of the body when they are stretched within physiological limits. The relaxing appears to vary and Hooke's law is not always observed. The different tissues vary in the time that they take to recover their former length.

The Relation of Adrenalin to Muscular Fatigue.—The highly practical and novel researches on this subject by S. Dessy and V. Grandis (*Arch. Ital. de Biol.*, May 31, 1904), were inspired by the following experiments and observations of other authors. In 1891-92 Abelous, Langlois and Albanèse, observed that animals deprived of the suprarenal capsules are incapable of performing prolonged muscular actions and that they rapidly succumb to a short exertion. These results the above experimenters attribute to the fact that the internal secretion of the suprarenals neutralizes the toxic products of the muscular contraction. This observation served to explain the clinical experience that individuals affected with Addison's disease present a marked degree of adynamia. Battelli found that during fatigue the quantity of adrenalin in the suprarenal capsules diminishes, and that during the hours consecutive to an intense degree of work, the suprarenal capsules contain an amount of adrenalin greater than the normal. This observer based these facts upon the hypothesis that adrenalin passes into the circulation in order to neutralize the depression produced by muscular work. He explained the later increase in the amount of adrenalin by the supposition that the organs, particularly the muscles and nerves, produce a proto-adrenalin, which the suprarenal capsules transform into adrenalin. The authors of the present paper, considering this explanation too complicated, sought more direct reasons for this phenomena. They studied the effect of adrenalin upon a muscle which had passed into fatigue. They found that

when, after a long series of contractions, the muscle has lost its power to contract, if 2 c.c. of an aqueous solution of suprarenal capsule be injected into the dorsal lymphatic sac (the solution being prepared by dissolving 5 gr. of dried suprarenals in 100 c.c. of distilled water), after from two to eight minutes, the muscle begins again to contract, and continues to do so for a period longer than that seen at the beginning of the experiment. On examining the graphic curve, it is found that the adrenalin, while neutralizing the effect of fatigue, does not do so entirely, for the renewed contractions are not as strong as those seen after a period of normal repose. This deficiency of strength is probably to be attributed to certain changes produced in the muscular fibers apart from the action of the toxic products of the muscular contratcion. The authors found that animals which have been for a long time in the condition of fasting, possess a greater susceptibility to the fatigue-neutralizing action of adrenalin. One might say that the suprarenal capsules, of all the organs, are the ones which are the most profoundly affected by fasting. Probably to the absence of the function of the suprarenals may be attributed the muscular debility characteristic of an insufficient diet. The researches of the authors show that a fatigued muscle, in spite of the large amount of work accomplished, has not in reality exhausted all its energy, since, without resting an instant, it can begin again to contract, by receiving a small quantity of adrenalin. It would appear that the latter drug neutralizes the action of the toxic substances produced during the muscular contraction. But the suprarenal capsules cannot counteract entirely the effect of muscular fatigue. One is lead to the conclusion that the muscular substances is affected by the contraction, so that, in spite of the protection afforded by the suprarenal capsules, the time comes when the muscle can no longer contract. It is therefore necessary to restrict the term "muscular fatigue" to the disability which cannot be overcome by adrenalin. From the study of the action of adrenalin on unstriated muscular fibers, the authors draw the general conclusion that this substance acts upon the contractility of protoplasm. The hemostatic power of adrenalin probably depends upon the fact that the latter, in neutralizing the products of contraction, permits the vasoconstrictor nerves to develop their entire activity and to keep the small vessels contracted for a long time. In the same manner may be explained the rapid and brief increase in blood pressure following the injection of adrenalin, which increase is dependent upon the action of this substance upon the myocardium and upon the muscular tunic of the arteries. The action of adrenalin is a transient one, since this secretion is rapidly oxidized by the arterial blood.

Intra-ocular Circulation and Intra-ocular Pressure. The pathology of glaucoma will probably be illuminated by new researches in the various factors that influence the pressure inside the eyeball. An interesting investigation into this domain has been conducted by E. E. Henderson and E. H. Starling (*Jour. of Physiol.*, August 22, 1904). They find that the intra-ocular pressure is a function of the pressure in the ocular blood vessels, and varies directly as this latter. The intra-ocular pressure rises and falls with the general arterial blood pressure, and is not appreciably affected by a certain degree of rise in the pressure in the great veins. Stimulation of the sympathetic (head end) causes a preliminary rise in intra-ocular pressure, due to contraction of the orbital unstriated muscle, followed by a slow fall of pressure occasioned by contraction of the intra-ocular blood-vessels. Stimulation of the peripheral end of the divided fifth nerve root causes a rise of pressure due to contraction of the orbital unstriated muscle. This effect is absent if the fibers coming to the Gasserian ganglion from the sympathetic nerve degenerated in consequence of preliminary extirpation of the superior cervical ganglion. There is no evidence of vasodilator fibers to the eyeball either in the fifth or cervical sympathetic nerves. Previous statements to the reverse effect are based on imperfect experimentation. The effects of adrenalin and nicotin on the eye vary according as the local or general effect in the blood vessels predominated.

The Union of Different Kinds of Nerve Fibers.—Of eminent practical importance from the viewpoint of recent surgical progress in the anastomosis of nerve fibers, are the results of the experiments of J. N. Langley and H. K. Anderson (*Jour. of Physiol.*, August 22, 1904), upon the limitations to the possibility of uniting different kinds of nerve fibers. The experiments were made on cats and rabbits. When the central ends of two limb nerves are joined, no functional union takes place between them; impulses set up in one nerve cannot pass across to the other. When the central end of a limb nerve has an opportunity of joining with two peripheral nerves, stimulation of one peripheral nerve, after complete severance of the conjoined nerves from the central nervous system, may cause contraction of the muscles innervated by the other. The authors consider this to be an axon reflex, set up in fibers from the central end, one branch of which has joined one peripheral nerve and the other branch joined the other peripheral nerve. When one of the peripheral nerves consists entirely of afferent fibers an axon reflex may still be produced by stimulating it. Since efferent nerves do not, so far as is known, unite with afferent fibers, the axon reflex obtained supports the view that regeneration takes place by a down growth of axis cylinders. The crural nerve can make functional union with the sciatic and can be artificially lengthened. This is in harmony with Bethe's observation that the sciatic can be elongated by joining it with the sciatic of the opposite side. The authors do not find that when the internal saphenous nerve is joined to the sciatic nerve there is produced a motor effect. The phrenic nerve when united with the cervical sympathetic, can cause the usual effects produced by stimulating the latter nerve. The authors confirm Mislavsti's result that the cervical sympathetic can unite with the recurrent laryngeal nerve and cause movement of the vocal cords. Also after union has taken place, section of the cervical sympathetic causes degeneration of the medullated fibers in the recurrent laryngeal, except for a few which arise from the superior laryngeal nerve. The cervical sympathetic can unite with the phrenic nerve and cause contraction of the diaphragm. It can also unite with the spinal accessory and cause contraction of the sternomastoid muscle. They do not find that either (*a*) the afferent fibers proceeding centrally from the ganglon of the trunk of the vagus, or (*b*) the afferent fibers proceeding peripherally in the great auricular nerve, or (*c*) cutaneous afferent fibers can unite with the peripheral end of the cervical sympathetic in such a way as to transmit nervous impulses to it or to the superior cervical ganglion. Nor do they find that the cervical sympathetic after excision of the superior cervical ganglion—can make functional connection with the fibers leaving the anterior end of the superior cervical ganglion. Preganglionic fibers cannot make functional connection with postganglionic fibers. They do not find that the postganglionic fibers leaving the anterior end of the superior cervical ganglion can make connection with the hypoglossal fibers supplying the tongue muscles, although they do this with the vasomotor

fibers of the hypoglossal. The following general conclusions are drawn: The central end of an efferent fiber can make functional connection with the peripheral end of any other efferent fiber of the same class, whatever be the normal actions produced by the two nerve fibers. There are three classes of nerve fibers as regards the possibility of their union: *A*, Efferent fibers proceeding from the spinal cord, *B*, Postganglionic nerve fibers (the efferent fibers given off by the peripheral ganglia), and *C*, Afferent nerve fibers. Functional union is not possible between fibers of Class *A* and Class *B*. With regard to the union of afferent nerves with efferent nerves and vice versa, the term functional union is inappropriate. The authors confirm the experiments of Schwann and Schiff, which show that in the nerves of the limb afferent fibers when joined to efferent fibers, do not acquire any motor action. The possibility is not excluded that afferent fibers may grow down the course of the efferent fibers, and form afferent nerve endings, which from character or position, are incapable of transmitting impulses to muscle, gland, or motor nerve-cells. The influence which impels the cut ends of various nerve fibers to grow to one another, appears to be of a chemioactic nature, which influence has numerous gradations. The nerve fibers of the three classes mentioned above are incapable of coalescing with one another. Whether the regeneration, which takes place when fibers of the same class are united is due to coalescence or to down growth, the authors regard as an open question, notwithstanding the interesting researches of Bethe.

Reaction of Thymus to Assimilation of Calcium Salts.—Like other authors, the experiments of F. SINNHUBER (*Zeitsch. f. klin. Med.*, Vol. 54, Nos. 1 and 2), lead him to believe that the thymus possesses no functions of value to postembryonal life. Its extirpation does not influence the absorption and assimilation of lime salts, and it stands in no relation with rachitis. The atrophy or hypertrophy of the thymus seen in this disease, is simply a manifestation of the same constitutional disturbance which causes the diminished amount of calcium in the bones. The ingestion of thymus glands has no influence upon the excretion of lime, but slightly increases the amount of nitrogen voided. Large doses of thyroidin, on the other hand, considerably increases the amount of calcium and nitrogen in the urine.

THERAPEUTICS.

Serum Treatment of Acute and Chronic Articular Rheumatism.—D. MENZER (*Münch. med. Woch.*, August 16, 1904), states that better results in the treatment of acute and chronic articular rheumatism have been obtained from the use of antistreptococcus serum than from any other medicine. Chronic cases, if not cured, are materially improved and in acute cases an endocarditis will heal more readily. As proof of the latter fact a case is cited which presented well-marked increase in cardiac dulness with presystolic and systolic murmurs at the apex during an acute attack, but two years after treatment there were no longer any definite signs of endocarditis. Since the serum may render acute chronic inflammatory processes, it should be used with caution in pericarditis, or marked pleurisy, or advanced mitral stenosis. In acute cases single doses of 5 c.c. should be employed, while if chronic, several periods of treatment are necessary. The other measures employed for rheumatism are also in place but salicylates need not be given.

A New Digitalis Preparation.—The great drawback in giving digitalis, lies in the fact that the drug is of varying strength and different preparations may thus give rise to a varying therapeutic effect. Though all the active principles of the drug are contained in digitoxin, the main glycoside of the leaves, this has not come into general favor, since insoluble and irritating and entirely unfit for hypodermic use on account of the necrosis it is liable to set up. By means of a very complicated process, M. CLOETTA, (*Münch. med. Woch.*, August 16, 1904), has finally succeeded in isolating an amorphous digitoxin which is much more soluble in water than the crystalline substance. It has been placed upon the market under the name digalin, in solution, of such strength that each cubic centimeter corresponds to 0.3 milligram, the average dose. After injecting, it is advisable to employ gentle massage and to cover the spot with a wet dressing. The physiological action is exactly the same as that of digitalis.

Active Principle of Male Fern.—The chief disadvantages of male fern as a therapeutic agent are its varying strength, disagreeable taste and irritating properties manifesting themselves in vomiting and intoxication. All the different principles occurring in male fern have been carefully tested by A. JAQUET. (*Therap. Monatshefte*, August, 1904). It seems that all the active properties are contained in the amorphous acid filmaron, which constitutes about five per cent. of the extract. Filicic acid and albaspidin are also anthelmintic but to a less extent and are also less abundant in the extract. The average dose of filmaron is 0.7 gmes. and patients very rarely experience other after-effects besides slight nausea or transient abdominal cramps. In efficacy it seems to be almost equal to the fresh extract from the rhizome.

Properties of Stypticin.—The hemostatic properties of stypticin, the hydrochlorate of cotarnin were not discovered by accident, but were predicted on account of the close relationship of this drug to hydrastinin. M. FREUND, (*Therap. Monatshefte*, August, 1904), has seen excellent results in climateric hemorrhage, hemorrhage of pregnancy fibroids and subinvolution, in reflex hemorrhage due to disease of the adnexa or the parametrium and in the congestive bleeding of young girls without pathological lesion. Recently a new preparation of stypticin has been placed upon the market under the name of styptol. It is the phthalate of cotarnin and possesses no advantages over stypticin since it is changed into the latter in the stomach. The usual dose of stypticin is 0.05 gm. six to ten times a day, but much more may be given, since it is in every way harmless.

Treatment of Anemia.—Arguing from the standpoint that chlorosis is an intoxication, C. S. ENGEL, (*Zeitsch. f. klin. Med.*, Vol. 54, Nos. 1 and 2), injected small quantities of the blood of a severely anemic girl into a rabbit, in the hope of bringing about the formation of an antibody. After a certain time, some serum was withdrawn from the animal, heated for half an hour to 58° C. and one cubic centimeter injected into the patient. The reaction following was very severe, but subsequent doses were better tolerated, so that only slight headache was complained after the eighth and last dose. Though the patient had continually lost ground with arsenic and iron medication, she picked up wonderfully during the two months the injections were given, and when seen, a year later, the blood contained 90 per cent. hemoglobin and 4.8 million red cells.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 24, 1904.

PRESENT POSITION OF GRAVES' DISEASE.

When about the end of the first quarter of the nineteenth century Dr. Robert Graves, of Dublin, described two cases of nervous disease suffering from special symptoms including rapid heart with prominence of the eyes and a goiter in the neck there was no thought that he had described an important nervous affection. Not for several years later were further cases of the same disease detected and described on the Continent. Even after it had come to be generally recognized that this was a special symptom complex, deserving a separate name in nosology, it was considered to be a rare condition. After three-quarters of a century there is a growing conviction that the disease is much more frequent than has been thought, that it may occur with any two of the classical triad of symptoms absent and that milder forms of the disease may be comparatively so latent as to require special care for their recognition.

While it has more than once been suggested that Graves' disease is not due to a disturbance of the thyroid gland but to some other ductless glands, there has always been a recurrence to the idea that the most probable basis of the affection is a superabundance of thyroid secretion in the system. Last year we called attention to Dr. McCallum's experiments of animals deprived of the parathyroids which seemed to show that an affection resembling Graves' disease developed in the deparathyroidized animals. We know, however, from experiences here in New York and elsewhere that the therapeutic suggestion made as a consequence of these observations to prescribe extract of parathyroids or the dried substance of these glands from animals for sufferers from Graves' disease, has not proved successful in practice. On the other hand, it is well known that the use of thyroid extract or desiccated thyroids always causes an exacerbation of the symptoms of Graves' disease and that therefore the possible etiology of the affection is the hypersecretion from this gland.

That there should be a functional disturbance of the thyroid, temporary in character leading to symptoms of Graves' disease, not necessarily severe, yet more or less typical and representing deviations from the normal health in nervous individuals, would not be surprising. The exactly opposite condition of myxedema, in which there is apparently a deficiency of thyroid secretion, occurs typically in those in whom the gland is absent, but milder forms of the disease and certain analogous manifestations have been known to occur without necessarily being accompanied by lasting changes in the soft parts or any serious constitutional disturbance. It is generally recognized now that functional disturbance of the thyroid with a tendency toward deficiency of secretion may produce a number of symptoms in children which are favorably affected by the administration of small amounts of thyroid extract or desiccated thyroid substance. During the period just before and after puberty the tendency exhibited by certain young people to take on an abnormal amount of flesh has been found to be associated with some disturbance of the thyroid secretion, which can be modified with good effect by the administration of thyroid material.

It is not surprising that milder cases of Graves' disease should occur with symptoms so latent or concealed under the mask of neurasthenia, or nervous weakness of some kind, that their real origin is not recognized. At times such cases may occur without noticeable goiter and a series of such cases have recently been published by Dr. William H. Thompson. Occasionally these cases without goiter, may be quite severe in their other symptoms. The theory of Graves' disease, which has met with most acceptance, is that some poi-

sonous material within the body is destroyed by means of the thyroid secretion. The presence of this toxic material in larger quantities than normal so irritates the gland that more thyroid secretion is poured out than is necessary with the consequent production of the symptoms of Graves' disease. It is probable that in some cases the thyroid fails to enlarge, even though it does respond to the irritation and that its increased secretion fails to be neutralized in the way usually provided for it by substances ordinarily absorbed from the digestive tract.

The most successful treatment of Graves' disease continues to be the careful management of the alimentary tract. It is a rule almost without exception that in Graves' disease there are annoying symptoms of gastric and intestinal indigestion. Alternating constipation and diarrhea is the characteristic history. Whenever the condition of the digestive tract is improved the symptoms of the affection almost invariably grow better and even symptomatic cures may occur. There always remains a tendency to relapse, showing that there probably was originally some pathological condition, either in the thyroid glands, or in the absorbent apparatus of the intestines, but the improvement that can thus be obtained is often very remarkable. It would seem that the modern clinician instead of grouping a number of puzzling cases with nervous symptoms and a marked tendency to rapid heart, under such vague terms as neurasthenia or nervous tachycardia, should bear in the mind the possibility of Graves' disease being present in these cases and should direct his treatment and announce his prognosis of the ailments of such patients with these considerations in mind.

ULCER OF THE DUODENUM.

While it was generally conceded that ulcer of the stomach was by no means infrequent until very recent years, it has been the custom to regard ulcer of the duodenum among the rarities of clinical experience. It is not only much rarer than ulcer of the stomach, but by a curious anomaly it is said that while ulcer of the stomach was much more frequent in women, ulcer of the duodenum occurred much oftener in men.

It appears, however, that the better part of our supposed knowledge of ulcer of the duodenum has been founded on lack of due information. Unless special symptoms called for it the duodenum was not often opened at autopsy and recent studies seem to show that many an ulcer in this portion of the tract has thus escaped discovery.

It is generally conceded that ulcer of the stomach may not infrequently run its course absolutely without any symptom, and many perforations of the stomach wall from ulcer have occurred without a single salient feature of the history that would indicate the presence of a gastric ulcer. The same has probably been even more common with ulcers of the duodenum. At the last meeting of the American Surgical Association Dr. W. J. Mayo and Dr. Christopher Graham, of Rochester, Minn., presented a clinical study of 41 cases of ulcer of the duodenum on which they had performed operations. The very fact that the service of one should furnish so many cases to report shows that this lesion is by no means as infrequent as has been thought. In more than one-fourth the cases there was coincident ulcer of the stomach. Indeed so commonly is the duodenal ulcer associated with severe gastric ulcer that Dr. Mayo advises that the incision for operation upon a case of gastric ulcer be planned with the idea of allowing careful investigation of the duodenal region. For this purpose he suggests that the incision should always be made well to the right of the median line.

The frequency of ulcer of the duodenum may demand more careful investigation as to another long-accepted idea with regard to its occurrence in connection with extensive burns. It is a text-book tradition that in these cases severe duodenal ulcers are likely to be found if the patient has survived the accident for some time. This relation is so well known that no one now makes an autopsy on a subject that has died from a burn without careful examination of the duodenum. The consequent investigation has led to the confirmation of the suspicion that duodenal ulcers have not been found in every case, but only in a notable proportion of the cases. Whether the finding of duodenal ulcer in these cases may not be only a coincidence due to the unsuspected frequency of a lesion which is not necessarily connected with the burn, remains to be determined; but there are many medical traditions that have been accepted on less trustworthy evidence than this.

In the meantime duodenal ulcer, like many other diseases formerly considered so rare as to be medical curiosities, must now take its place among the possibilities always to be considered when there are obscure abdominal symptoms

Affections of the biliary tract are receiving so much attention that discomfort and tenderness in this abdominal quadrant is almost sure to be taken for some biliary complication and the most careful differentiation will be needed. The adhesive inflammation around a duodenal ulcer is likely to involve the bile passages, so that the primary lesion may be impossible of determination. There is no doubt, however, that some of the supposed cases of malignant disease in this region have been chronic inflammatory and cicatricial conditions arising from old but unsuspected duodenal ulcers. Thus another reason for hope in what used to be considered fatal cases is now held out.

ECHOES AND NEWS.

NEW YORK.

Cornell University Medical College.—Dr. Frederick Whiting has been appointed Professor of Otology in place of Dr. Gorham Bacon, resigned. Dr. Adolf Meyer has been appointed Professor of Psychiatry in place of Dr. Allen McLane Hamilton, resigned. The students registered for the coming first year class, to begin work on September 28, are largely in excess of the numbers of any previous class at this date, and it is exceedingly gratifying to note that the campaign carried on so vigorously in the medical press for better preliminary education is beginning to bear fruit, for 78 per cent. of those applying present evidence of having had chemistry and physics.

Pharmacists Protest.—Pharmacists all over the city are preparing earnest protest against the recent amendment to the Sanitary Code, prohibiting the sale of carbolic acid at retail except in the form of four or five per cent. solution. The Kings County Pharmaceutical Association has already appointed a committee to arrange with other pharmacists' organizations in the greater city for common appeal. The complaint of the druggists is that the prohibition of the sale of the acid, while it will not accomplish its purpose, that of making suicide more difficult, will inflict a great hardship on the public, who use carbolic acid more than any other agent for disinfectant purposes. At the same time they assert that an intending suicide can go to a wholesale drug house and buy the acid in the original package without question, and a child can do this as easily as an adult. In the notice of the new carbolic acid regulation it is stated that, while the Department of Health does not desire to pursue the drug trade particularly, if carbolic bottles bearing the name of a drug firm are found by the Coroner's office by the side of suicides, the department will take action against such druggists through the District Attorney's office.

Columbia's Opening Exercises.—The exercises to mark the opening of the one hundred and fifty-first academic year of Columbia University, will be held in the University Gymnasium on Wednesday, September 28 at 3 P.M., and will be open to the public. The address will be delivered by Professor Robert Simpson Woodward, Dean of the Faculty of Pure Science, whose subject is to be "Academic Ideals." The exercises this year will be marked by the presence of the Archbishop of Canterbury, one of whose predecessors in office was the first *ex-officio* trustee named in the original charter of King's College. Upon the conclusion of the exercises in the Gymnasium, the Archbishop of Canterbury will formally dedicate to religious uses the site upon which the new University Chapel is to be built. The Archbishop will be escorted to his place upon the platform in the Gymnasium by an academic procession consisting of the officers of instruction and of the members of the boards of trustees of the several corporations included in Columbia University. Seats will be reserved upon the floor of the Gymnasium for the students, grouped according to schools, and also for members of the families of the trustees and officers of instruction.

College of Physicians and Surgeons.—The opening exercises of the academic year 1904-5 will be held in the Lower Lecture Room on Thursday, September 29, 1904, at 3 P.M. After a brief address of welcome by the President of the University an address will be delivered by John G. Curtis, M.D., Acting Dean and Professor of Physiology, upon "Our Medical Training in the Light of Ancient Error."

PHILADELPHIA.

Typhoid Again Increases.—During the past week 134 cases of typhoid fever were reported, an increase of 34 over the preceding week. The effect of filtered and mixed water in West Philadelphia is being carefully watched.

Trolley Cars to be Improved.—The Philadelphia Rapid Transit Company is at last beginning to remove the plush and carpet-covered seats from their cars and replace them by rattan. This was the subject of a great deal of comment during the past year by individuals and societies, particularly those for the prevention of tuberculosis. Reforms will come if the people persist in demanding them.

Hospital Patients Alarmed in Queer Way.—During the severe storm of last week a limb blew against the steam whistle of the Pennsylvania Hospital engine house and the shrill whistle, which is used only in emergency cases, was kept blowing for ten minutes while the storm was at its height. The patients were all alarmed and a negro who had been stabbed some days before died during the excitement.

No Law Against Selling Babies.—Though the papers of the city have recently exposed several places where infants are bought and sold, officials say there is at present no law by which those engaged in the business can be prosecuted. The only hold is in arresting the people for cruelty and this is seldom possible as the infants are cared for perhaps better than at home. Instances are known where infants are loaned over night for $3 to $5.

Opening of Medical Colleges.—The Woman's Medical College of Pennsylvania opened on Wednesday, September 21. The exercise included inspection of the new pavilion hospital and dispensary. In the Freshman Class are two students from India. The Jefferson College opens September 26, the Medico-Chirurgical September 28, and the University of Pennsylvania on September 30. The Philadelphia Polyclinic opens on October 3.

CHICAGO.

First Aid to the Injured.—It is said that the casualty list incident to the rush of modern industrial life has grown so appalling in the last year that an organized effort is being made in Chicago to instruct individuals in the best methods of giving first aid to the injured. The Chicago First Aid Society, consisting of prominent doctors and laymen, which has been formed for that purpose, is pushing its work. The course of public instruction will consist of a series of lectures which will include elementary lessons in anatomy and physiology. In-

struction will be given in bandaging and how to treat shocks of electricity. Methods of treating broken bones, sprains and dislocations will also be taught. The medical board, which will award certificates and badges to graduating members, is made up of Drs. Nicholas Senn, Charles Adams, R. N. Foster, Arnold C. Klebs, Henry B. Favill, James B. Herrick, N. S. Davis, S. C. Stanton, John Ridlon, John B. Murphy, Wm. E. Quine, and Geo. Webster. No charge is to be made for the instruction.

Insanity on the Increase.—According to interviews with several physicians, in the Chicago *Evening Post* of recent date, this disease is increasing at an alarming rate. Dr. Warren H. Hunter, of the Chicago Detention Hospital, said: "It is a mistake to suppose that many patients become deranged from the strenuous life of the city and overwork—it is not the work, but the stimulants used by man to push him on, against the warning of nature, like whipping an exhausted horse into action. If the overworked man would not keep up on drugs nature would give him the needed rest in the form of an illness, but under the whip lash of stimulants, when he does collapse, having no reserve resistance, he often becomes deranged."

Benefit Concert for Samaritan Hospital.—On the evening of September 16, a benefit concert for the Samaritan Hospital was given at the Coliseum. The Coliseum Company donated the use of its building, and Brook and his band furnished one of the best programs of the season. It is the only opportunity this year that the public has had to help this hospital. Though a charity, the Samaritan Hospital is doing good work. In the absence of a down-town emergency hospital, practically all of the victims of accidents which happen in the down-town district are taken there. The police have been accustomed to take unknown victims of accidents to the Cook County Hospital, but many lives have been saved by hurrying to the near-by Samaritan, where immediate medical attention may be had. At the time of the Iroquois disaster, the Samaritan cared for twice as many of the injured as any other hospital. No patient has ever been refused at the hospital.

Sir Felix Semon Entertained.—This distinguished physician was given a dinner by the Chicago Laryngological and Climatological Society at the Chicago Club, September 15.

Appointment of Dr. Wald.—Dr. O. E. Wald has received the appointment of Chief Surgeon of the Bethesda Hospital.

Chicago Day at the Louisiana Purchase Exposition.—Drs. Arthur D. Bevan and James Chvatal have been nominated on the committee to represent Chicago on October 8.

CANADA.

Canadian Medical Association. -The thirty-seventh annual meeting of the Canadian Medical Association was held in Vancouver, B. C., on August 23, 24, 25 and 26, under the Presidency of Dr. Simon J. Tunstall, of that city, the General Secretary being Dr. George Elliott, of Toronto. It was the first time that the Association had held a meeting in the Pacific province, and every expectation of a good and a largely attended meeting was fulfilled. The following guests were introduced to the meeting at the opening session: Mr. Mayo Robson, of London, England; Prof. E. C. Dudley, of Chicago; Prof. W. Japp Sinclair, of the Victoria University, of Manchester; Dr. McGillivray, of Edinburgh, Scotland; Dr. C. H. Mayo, of Rochester, Minn.; Dr. Oviatt, of Oshkosh, and Dr. Kenneth McKenzie, of Portland, Oregon. Mayor McGuigan, of Vancouver, who is a graduate in medicine of McGill University, delivered an address of welcome on behalf of the citizens of Vancouver, and he was followed by Dr. J. C. Davie, of Victoria, B. C., vice-president of the British Columbia Medical Council, who delivered the address of welcome for the profession of British Columbia. Dr. R. E. McKechnie, of Vancouver, proposed a resolution favoring the establishment by the provincial authorities of each of the provinces of Canada, of sanitaria for the treatment of cases of tuberculosis, which resolution was carried unanimously. The General Secretary, Dr. George Elliott, of Toronto, submitted his annual report. He urged that the Association be reorganized with branches throughout the Dominion. Dr. C. J. Fagan, of Victoria, B. C., secretary of the provincial Board of Health of British Columbia, read a paper on Patent Medicines, which brought out a keen discussion and resulted in the formation of a special committee to draft a resolution on the subject. This committee subsequently reported in favor of memorializing the Federal Government with regard to the formulæ being printed on all patent medicines offered for sale in open market. When the afternoon session was called to order, President Tunstall read the following telegram from Dr. Wolfred Nelson, of New York, which elicited much applause: "Thanks for kind invitation. I greatly regret cannot attend meeting. The press here, medical and lay, refers triumphantly to Osler's appointment as Regius Professor of Medicine at Oxford. King Edward approved it. Osler has accepted for next year. God bless dear old Canada, McGill and Osler." Dr. R. E. McKechnie, of Vancouver, then delivered the Address in Medicine. Mr. Mansfield, Fleet Surgeon on H.M.S. Grafton, was down for the exhibition of a new color-test apparatus, which in his absence was explained by Dr. Glen Campbell, of Vancouver. Dr. Kenneth McKenzie, Portland, Oregon, then read a practical and interesting paper on Movable Kidney, and was followed by Dr. Robert H. Craig, of Montreal, who reported several interesting and rare cases of a nasal nature. In the evening at the Hotel Vancouver, a conversazione was given by the local members of the Association, which proved a brilliant affair. At the morning session of the second day, Mr. Mayo Robson delivered the Address in Surgery, accompanied by a lantern demonstration, on the pancreas and the diseases of that organ. Of the many good papers and demonstrations of the meeting, this was undoubtedly the best, attracted a full representation of the members present, and was listened to with rapt attention throughout. At the conclusion a cordial vote of thanks was tendered Mr. Robson, moved by Dr. F. J. Shepherd, of Montreal. Following this was a paper read by Dr. Shepherd on Hernia of the Bladder complicating inguinal hernia, which was discussed by Dr. A. A. Macdonald, of Toronto, Dr. H. Meek, of London, Ontario, Dr. Secord, of Brantford, and Dr. Eagleson, of Seattle. Dr. S. R Jenkins, of Charlottetown, P. E. I., then reported a Case of Hyperthrophy of the Breasts. At the afternoon session, Dr. J. W. Sterling, of Montreal, contributed a paper on Diseases of the Eye, and was followed by Dr. Cruickshank, of Windsor, Ont., with a paper on Therapeutic Hints from Bacteriology. A reception was held in the afternoon by the ladies of Vancouver at Pender Hall, and in the evening the President delivered the annual presidential address, dealing mostly with questions pertaining to the medical politics of the Dominion of Canada. Following the presidential address, Dr. E. C. Dudley gave a very able address in Gynecology, illustrated with lantern slides, which proved one of the features of the meeting and was very much appreciated by all present. Following Dr. Dudley's address, the plans of the fine new hospital which Vancouver is erecting were projected on the

canvas, which soon made it apparent that Vancouver promises to have the finest hospital in the Dominion. At the morning session of the third day Dr. C. H. Mayo, of Rochester, Minn., read an able paper on Tuberculous Peritonitis. He was followed by Dr. Henry Howitt, of Guelph, Ont., who, as usual, had something new to report. This time his subject was: Meckel's Diverticulum, with a Report of Cases. Dr. C. W. Wilson, of Montreal, then read a paper on The Results (after one year) of the Lorenz Reposition of Congenital Dislocation of the Hip. This was illustrated by a number of radiographs. Dr. E. R. Secord, of Brantford, Ont., contributed a paper on Operative Treatment of Spina Bifida. On the afternoon of the third day the visiting delegates were taken to the salmon canneries at New Westminster and Steveston on the Frazer River, the annual banquet being held in the evening at the Hotel Vancouver. A pleasing feature of the meeting was the very large delegation from the Maritime Provinces. The local members who formerly claimed their homes in the Provinces, down by the Atlantic, took advantage of the presence of so many of their former confrères in Vancouver, and tendered them a special address of welcome. The morning session of the fourth day, as usual, was devoted to the general business of the Association. The first item on the program was the reception of the report of the Nominating Committee. This was presented by Dr. F. J. Shepherd, of Montreal, the chairman, and on being read was adopted entire. It was as follows: Place of Meeting in 1905, Halifax, Nova Scotia. President, Dr. John Stewart, Halifax. Vice-Presidents: Prince Edward Islands, Dr. McLaren, Montague Bridge; Nova Scotia, J. B. Black, Windsor; New Brunswick, A. B. Atherton, Fredericton; Quebec, Jos. E. Dube, Montreal; Ontario, H. Meek, London; Manitoba, W. S. England, Winnipeg; North West Territories, H. C. Wilson, Edmonton; British Columbia, R. E. Walker, New Westminster. Local Secretaries: Prince Edward Islands, H. D. Johnson, Charlottetown; Nova Scotia, G. C. Jones, Halifax; New Brunswick, T. D. Walker, St. John; Quebec, J. D. Cameron, Montreal; Ontario, D. Stuart, Palmerston; Manitoba, Dr. Popham, Winnipeg; North West Territories, Dr. Hewittson, Pincher Creek; British Columbia, A. S. Monro, Vancouver. General Secretary, George Elliott, Toronto. Treasurer, H. B. Small, Ottawa. Executive Council, Dr. G. M. Campbell, Halifax; Dr. Jas. Ross, Halifax, Dr. C. D. Murray, Halifax.

The usual votes of thanks were passed and after the meeting adjourned, the Canadian Medical Protective Association held its annual meeting. The President, Dr. R. W. Powell, of Ottawa, took the chair, and read the annual report. This organization now has some three hundred members. A satisfactory report was made, and some changes were also made in the constitution. The office of treasurer was abolished and the secretary was empowered to act as treasurer and secretary. The British Columbia Medical Association also held a business meeting and elected Dr. W. D. Brydeon-Jack as President for the ensuing year and the place of meeting in 1905, Vancouver. It is generally understood that the British Medical Association will meet in Toronto in 1906, and that there will be a conjoint meeting of that and the Canadian Medical Association. Altogether the meeting at Vancouver was a pronounced success in every particular. It was the third largest meeting in the thirty-seven years' history of the Canadian Medical Association, being only surpassed by the meeting in Montreal in 1902, and the meeting which was held in London, Ontario, last year.

GENERAL.

Berlin School Children Examined.—This year, for the first time, all the children in the schools of Berlin were examined as to their health. There were fifteen thousand children and thirty-six examiners. The results were astounding. Ten per cent. of the children were found insufficiently developed in body or mind, and had to be excluded for half a year or longer; sixteen per cent. were not strong enough to attend school, owing to the debilitating effect of scarlet fever and other diseases; fifteen per cent. suffered from anemia; five per cent. had tuberculous trouble.

Compulsory Vaccination at Colon.—In order to prevent the introduction of smallpox an ordinance regarding compulsory vaccination has been passed and promulgated by the chief sanitary officer. The isthmus has been remarkably free from this disease since the epidemic which prevailed along the coast in 1903, at which time vaccination was very generally practised. In the British West Indies vaccination has long been compulsory.

Sex and Brain.—Dr. J. de Körösy, director of municipal statistics at Budapest, read a paper before the British Medical Association, giving the results of twenty-seven years of observation in the schools of Budapest regarding the relative intellectuality of the sexes. He found equality to exist in the earliest school years, followed by a gradual increase, considerably more rapid among the girls, so that at the end of the school period the results of brain tests were all in favor of the female sex. His conclusion was that the feminine intellect developed more rapidly than the masculine, but as the great work of human progress has been accomplished by males, it was fair to assume that there was an early turning point where the intellectual activity of women seemed to be arrested.

Wounds From Japanese Small-Arms.—Interesting reports have been made by Russian surgeons concerning the effects of Japanese bullets upon the soldiers of the armies of the Czar. These surgeons say that the balls from the rifles of the warriors of the Mikado are of such size, shape and weight, that they make small, clean wounds, and many of the Russians who are put out of the fighting on battlefields are speedily restored to a sound condition. It is not denied, however, that the balls are effective enough for practical purposes in crippling and disabling infantry while the clash of arms is actually in progress, and he would be cruel and pitiless, indeed, who would desire a higher death rate among the opponents of the island empire.

Diphtheria in Newark.—The Board of Health will adopt drastic measures in an effort to prevent the spread of diphtheria in Newark. There has been an increase in the number of cases in the last two weeks, and it is feared, now that the schools have opened, that a still greater number of cases may be reported. In the week ending September 3, there were 27 cases of diphtheria in the city, and in the week ending at noon, September 17 of the present year, 53 cases were recorded.

University of Vermont Buildings.—In a circular letter recently addressed to the students and friends of the Medical Department of the University of Vermont, Dr. H. C. Tinkham, dean of that department, announces that the new college building, costing $100,000, will be completed May 1 next. The classes for the coming session will be adequately accommodated in temporary quarters until then.

OBITUARY.

Dr. Henry Ridgely, president of the Farmers' Bank of Delaware, and one of the wealthiest citizens of the State, died suddenly at his home in Dover, Del., on September 17. He was ninety-seven years of age. Dr. Ridgely was graduated from St. Mary's College, Emmittsburg, Md., and received his medical education at the University of Pennsylvania. In 1856 he was a delegate to the Cincinnati convention which nominated James Buchanan for the Presidency. The Delaware Legislature appointed him to represent the State in the Peace Congress held in Washington in 1861.

Dr. John L. Gormly died at his home, No. 430 Ocean Parkway, Brooklyn, N. Y., on September 7. He was born in that section of Brooklyn, thirty years ago. He was graduated at the Long Island College Hospital and later served on the staff of St. Mary's Hospital. He belonged to the Medical Society of the County of Kings.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Regular Stated Meeting, held Thursday, May 5, 1904.

The President, Andrew H. Smith, M.D., in the Chair.

The scientific business of the evening consisted of a discussion of the treatment of diffuse peritonitis held under the auspices of the section on surgery.

Diffuse Peritonitis.—The paper of the evening was read by Dr. Joseph A. Blake, who said that the opportunities for seeing diffuse peritonitis at Roosevelt Hospital were frequent because of the amount of emergency work, and that to surgeons in hospitals where no emergency cases came the number might seem excessive in frequency. Diffuse peritonitis he considered as a varying term for which there should be considered to be two forms of disease. One localized through spread beyond its original focus of infection. In this the spread of infectious material was limited by adhesions of the peritoneum and there was true abscess formation. In the second form this limitation did not exist, though here again, according to the time at which the affection was observed, a division must be made. In some cases all parts of the peritoneum are not involved. This was usually because sufficient time had not passed for the process to spread. In the other form of the affection all parts of the peritoneal cavity, except perhaps the smaller peritoneal cavity, were affected. Dr. Blake does not include under cases of diffuse peritonitis the merely serous peritonitis that constitutes the milder form of the infection.

Time for Operation.—With regard to the time for operation there has come a distinct change of view in recent years. The best rule now would seem to be to operate as early as possible. There is no waiting for a reaction that never comes. In this way there is much less shock because nothing can hurt the patient more than wide involvement of the peritoneum. If the affection has become limited, drainage can be made more effective. The less peritoneal surface invaded the better the prognosis. Other points of treatment have also changed in very recent years.

Present-Day Technic.—With regard to the washing out of the peritoneum, practically all are agreed on the usefulness of this procedure, but there is one important consideration. It must not occupy too much time. Delay with exposure of the intestines seriously injures their function, disturbs peristalsis and always increases the mortality. All manipulation of the intestine has this same effect. The ratio of deaths, indeed, may be said to increase regularly with the amount of exposure of the intestines and the handling they have been exposed to. It is the effect of this observation that has made meteorism much less of a bugbear than it used to be. For washing out, a hot saline solution is the best, but if it is poured in the ordinary way through a tube it increases intra-abdominal pressure and causes partial evisceration. It is often hard to get the intestines back under these circumstances. Accordingly Dr. Blake uses a large tube with an exterior outflow tube. From the character of the evacuated water it can easily be seen whether the abdominal cavity is clean. The evacuation is accomplished by means of siphonage and this serves to remove fibrin from the intestines and take away other slightly adherent material.

Drainage.—In many cases after the abdomen has been thoroughly cleaned out the peritoneum can be left to itself and no drainage is required. It must be remembered, however, that infectious material is in the abdominal cavity and that during the course of the lavage some of it may find its way over the freshly cut surfaces of the incision. This will cause suppuration. Hence, even when it is not considered advisable to use deep drainage, a drain half an inch below the surface of the peritoneum will often save the delay in convalescence incident to infections of the abdominal wound.

Postoperative Technic.—The guiding principle is to give the abdominal tissues and the gastro-intestinal tract as complete rest as possible. Hence the stomach is washed out in those cases in which there is nausea, and no food is given until the nausea disappears. If patients are weak, injections of hot saline solution are made, and if patients are very restless, morphine is employed. Where during the course of the operation the intestines are found widely distended and evidently full of gas, not passing material as they should, an opening is made in them and the contents allowed to escape, the incision being afterward closed by a purse-string suture. Dr. Blake has recently seen a trocar for the performance of enterostomy in these cases in which meteorism exists, the trocar causing after a time adhesion to the abdominal wall, but the fistula closes easily afterward.

Elevation of Bed.—If the drainage is employed from the pelvis of the patient then the head of the bed should be elevated. Undoubtedly the action of gravity favors the flow of fluid material toward the end of the tube in these cases and this mechanical factor may prove an important aid. Where the drainage tube is inserted high up in the abdominal cavity, that is above the umbilicus, the foot of the bed is raised and this manipulation has proved helpful.

Illustrative Cases.—Dr. Blake described certain of his cases in which special details seemed of interest. In one case of perforation of gastric ulcer, the patient was not operated upon until forty-eight hours after the perforation had occurred. The contents of the stomach were found in the peritoneal cavity, which was also full of pus. This patient improved after the operation, but succumbed on the fourth day. Another case of gastric ulcer, seen twelve hours after the perforation, though there was a lot of bile and stomach contents and pus, free in the peritoneal

cavity, recovered. The perforation in this case was at the pylorus and in repairing the rent the pylorus had practically to be closed. Accordingly a posterior gastro-enterostomy was made and the patient went on to uninterrupted recovery. In another case of diffuse peritonitis the peritoneum was found covered with spots of fat-necrosis. The symptoms in this case looked so serious that the abdominal cavity was not washed out after the operation. It seemed useless to do so. The patient, however, made a rapid and uninterrupted recovery.

Appendicitis and General Peritonitis.—In eleven cases of appendicitis general peritonitis was found and out of these three eventually proved fatal. The first of these was an alcoholic patient and very obese and death occurred on the eighth day. The second was a young physician who was in rather poor health. Before the operation he had been jaundiced and the case looked very unfavorable. Death took place on the sixth day. In this case the abdomen was reopened when the symptoms became bad after the period of relief afforded by the operation, but this did not give any further relief.. As a rule Dr. Blake has not seen any good from reopening the abdomen. One alcoholic patient, in whom there was widespread diffuse peritonitis, recovered in spite of double pneumonia. In cases of typhoid perforation Dr. Blake has found the use of the two-way tube for lavage especially satisfactory. With regard to drainage in these cases, as he acquires more experience, his drains become smaller. In Dr. Blake's experience, general peritonitis due to an infection from the Fallopian tube is apt to be a little more fatal in its result than that from any other source in the abdominal cavity. His own experience has shown him that there is a large balance of mortality in favor of no drainage, or only of superficial drainage.

Early Diagnosis.—Of course the most important element in the prognosis of these cases is early diagnosis, so that the cases may come for operation early. As a rule, the earlier the diagnosis and operation the less the mortality. In perforation of the stomach or of the pylorus through an ulcer, if the patients come to operation within twelve hours, there is practically no mortality. The outlook is very favorable in typhoid cases also, if the diagnosis be made early. Early removal of the appendix whenever there are threatened symptoms is also an excellent rule. Where there was perforation of the appendix with spreading peritonitis, a few years ago surgeons were satisfied to save one-third of the patients. Now it is felt to be a misfortune to lose one-third of them. Spreading peritonitis, that is, cases in which the affection has not yet reached the limits of the peritoneal cavity are seen oftener now by the surgeon, because of the improvement in diagnosis which brings them earlier into the surgeon's hands. Where the mortality used to be 60 per cent., it is now less than 20 per cent.

Conclusions.—As a result of his experience, Dr. Blake considers that an early operation is advisable in all cases of diffuse peritonitis. This operation should be done rapidly and with as little manipulation of the intestines as possible, but should be done through a rather large incision. Lavage with large quantities of normal salt solution seems to add distinctively to the favorable results in these cases. The surgeon will omit drainage wherever possible and will find it better to employ superficial drainage, that is, only just enough to protect the edges of the incision, rather than deep drainage in all cases where there has not been an extreme infection of the peritoneum, continued over a prolonged period.

Discussion of Drainage.—In opening the discussion, Dr. George Brewer said that there is no unanimity among surgeons as regards the use of drainage for diffuse peritonitis. Years ago, McBurney treated these cases by putting in a number of wicks of gauze in many directions through the peritoneal cavity. He saved many of his cases, indeed seemed to have marvelous results, yet he lost many cases also. Then came the era when drainage seemed to be the most important factor in the treatment of these cases. Large incisions were made, and even, at times, incisions on the right as well as in the appendiceal region, simply for purposes of drainage. After that came a period when some surgeons completely eviscerated the patient and wiped off every coil of intestine. It was owing to the initiative of Dr. Morris that the surgeons generally got away from this mistaken notion of exaggerated interference and returned to simpler methods. Now, the reaction has reached a point where a small incision and a small cigarette drain are considered quite sufficient. The prime factors that make for success in the treatment of general peritonitis now are considered to be rapidity of operation, little interference with the intestinal contents and a cigarette drain for the pelvis. Dr. Brewer does not consider that it is ever safe where there has been real purulent peritonitis, to close the abdomen without drainage.

Removal of Products.—Dr. Eliot said that all surgeons are now agreed on the necessity for rapid operation in these cases, but also consider that certain indications for treatment must be fulfilled. The important points are removal of the cause of peritonitis and also of any products of inflammatory reaction that may be present. This latter purpose is accomplished by lavage with the least possible disturbance of the intestine. Instead of the old method, however, of leaving the abdomen full of normal salt solution, there is a tendency now to have the abdominal cavity dry. Drainage is being made by smaller and smaller amounts of gauze and there seems a tendency to do away with even this. Dr. Eliot considers that a double incision—one intermuscular, the other in the median line just above the symphysis pubis give the patient a better chance for life. The opening in the muscles must be kept open by means of a good bit of drainage material.

Local Abscess.—Whenever nature has established a local abscess, there seems no necessity for drainage. The case has been taken care of much better than the surgeon can do it. The cavity will be obliterated and the muscles much less weakened by simple evacuation. With regard to the necessity for drainage where peritonitis is more general, a recent case illustrates its advisibility. The patient was suffering from general peritonitis and from a condition of almost complete absence of pulse, yet was restored to a good general condition by operation, lavage and drainage. Four days after the beginning of his recovery the drain was removed and there was a relapse into a very unfortunate condition. All the symptoms subsided, however, with the reinsertion of the drain. If surgeons had the facilities for knowing the nature of the germ present in certain cases of peritonitis, they would be in much better condition to judge as to the necessity for drainage. In nine out of ten cases there would seem to be very little necessity for drainage; in the tenth case, however, failure to use the drain would almost surely be fatal.

Prognosis and Appearance of Intestines.—In certain cases the intestines are distended, but still retain their glossiness, in others they have acquired a sodden look, having lost their shiny smoothness and seem to be as far removed from the lively hue of the normal intestine as can well be imagined. Whenever the sodden appearance of the intestines is noted, in Dr. Eliot's experience, there is distinctly a bad prognosis. This is true even though the patient's general condition may not seem to portend a serious result and even though there may seem to be a favorable reaction after the operation. There is evidently, in these cases, some disturbance of the important function of the peritoneal coat of the intestine by which vital resistance is kept up.

Virulent Forms of Peritonitis.—Dr. Boldt said that gonorrheal and tuberculous peritonitis are the most serious forms with which the surgeon has to deal. There is often a rapid peritonitis which develops from acute gonorrhea. The peritoneum in young, healthy persons, however, seems to have a reasonably good resistance to the gonococcus and the infection becomes walled off and they recover. The pneumococcus, when it exists in the female pelvis, is apt to be especially virulent. If the tube, for instance, affected by the pneumococcus be ruptured during operation, a fatal peritonitis is very likely to develop, if the peritoneum should become infected. With regard to tuberculosis of the peritoneum, statistics are apt to be misleading. Patients may be much improved for months, be reported cured, and then have a relapse of the condition which proves fatal. The form of tuberculous peritonitis present is important. Dry peritonitis is the most serious. On the other hand serous peritonitis, where there is considerable ascitis is the most amenable to treatment.

Gynecological Peritonitis.—Dr. Boldt said that peritonitis, from the forcing of fluid through the tube into the peritoneal cavity, during the course of douching the uterus, is usually not severe. It depends, of course, to a great extent on the irritating nature of the fluid and the possibility of there having been any infectious material in the uterus or tube, before the injection was made. Practically all that is needed for its treatment, however, is the application of cold and the securing of absolute rest. With regard to peritonitis due to foreign bodies in the peritoneal cavity much more radical and immediate treatment is needed. Usually this occurs as the result of tumor with a twisted pedicle or from a gangrenous cyst as a consequence of pressure or torsion. The rule must be in these cases to operate as soon as symptoms are serious, for delay only makes the condition worse and weakens the patient rendering the eventual outcome of operation more doubtful.

Drainage in Women.—While there may still be doubt as to the advisibility for the employment of drainage in men suffering from diffuse peritonitis there seems to be no doubt in the case of woman, that drainage should be made through Douglas's *cul de sac*. This is really a natural drainage outlet and thorough evacuation of materials within the peritoneal cavities can be secured. The material used to secure drainage, however, should not go all the way into the peritoneal cavity but should only keep the tissues just outside of it freely open. In order to assist drainage the head of the bed should be elevated and the best of results are accomplished by this simple manipulation, which of late has come to form so important a bit of technic in the treatment of peritoneal conditions.

Cellular Resistance.—Dr. Robert T. Morris said that two things must always be considered in the treatment of peritonitis. The first indication is to remove mechanically whatever is causing the peritonitis which would seem to indicate that washing and thorough cleansing of the abdominal cavity must be the rule. There is, however, a second principle of treatment that must not be lost sight of. This is that the cells of the peritoneum are perfectly capable of disposing of an immense amount of infectious material, if they are only not overloaded with it. Anything that injures these cells then must be considered as a serious disadvantage for the patient. If we were to take one of the healthiest policemen in New York and insert half a yard of gauze into his peritoneal cavity he would almost surely not be able to walk to-morrow. The result of the shock of the presence of this material would prostrate him. Therefore, in the case of an ailing patient the great care must be exercised not to subject him to such irritation unless it be absolutely necessary. It would seem, however, that lavage of the peritoneal cavity with careful precautions to keep the incision open for some time does no good. Certainly the present tendency is toward doing as little as possible that is absolutely consonant with fulfilling surgical duty. The present surgical rule might be stated: Get into the abdominal cavity as soon as possible, get out as soon as feasible and leave the patient as much as possible to himself. There are surgeons who close the abdomen without any drainage. There are, in this, however, two extremes, Scylla and Charybdis; and both must be avoided.

Immediate Closure.—For two years Dr. Morris has preferred to do, in most cases, an immediate closure of the abdomen. A large portion of these cases recover very well. Perhaps, indeed, better than by any drainage method, however well arranged. On the other hand, some of the patients develop abscesses in the abdominal wall itself, and especially in the fatty layer of it, and these abscesses are particularly difficult to treat successfully and they are apt to hang on for a long time. Sometimes it takes as long as three months for the patient to get over them entirely. In cases where immediate closure is made the patient runs a temperature for several days and the surgeon is apt to be discouraged at first. Yet the method gives good results.

Peritoneal Endothelium.—Anyone who knows the construction of the outer layer of the peritoneal covering of the intestine, with its delicate endothelial cells lying side by side and the arrangement of the openings of lymphatics between them will realize how easy it is to disturb nature's protective mechanism of absorption here. Any handling of the intestines is almost sure to disarrange these delicate cells and close the lymph channels. Hence any active drying of the intestines is certainly wrong. Even lavage under pressure would seem a doubtful procedure and anything that causes portions of the intestines to find their way outside the abdominal cavity, whence they must be forced back again, is almost sure to do the patient more harm than good.

Dr. Wyeth said that a brief operation, a small incision and a minimum of traumatism are the ideal in the modern operation upon the peritoneal cavity. His own practice is to wash the abdomen out under pressure by means of a reservoir rather high above the patient. Drainage is, however, extremely necessary. Most of his septic cases have occurred from unsatisfactory drainage. A good rule is to keep the head of the bed up and drain from the pelvis.

Dr. Walker said that success in the treatment of peritonitis depends upon the condition that is found. If the peritoneal covering of the intestine is dark and sodden without the shiny glistening appearance of life, then the prognosis is bad. Any serum that is left in the abdominal cavity is almost sure to act as a culture medium for micro-organisms. Hence the necessity for drying out the peritoneal cavity. Where there is much exudation, a large drain should be employed.

Dr. Wiggin said that a large drain only gives occasion for additional adhesions. A small drain helps the abdomen to get rid of infected, material, however. The absence of such drainage is almost sure to lead to infection of the abdominal wound. Where there is distention of the intestines from accumulation of gas, the intestines should be opened, for this gives great relief to the patient's respiration. Respirations of sixty to the minute will sometimes drop to thirty-five immediately after relief was thus afforded.

Dr. Farquhar Curtis said that when lavage was first introduced he believed in the use of a large tube and so had special Chamberlain tubes made for himself. Now he uses smaller and smaller tubes and less drainage and gets better results. Undoubtedly one feature in these better results is the smaller incision and the less traumatism inflicted. The peritoneum is perfectly capable of caring for infectious material, if it is not injured.

Long Incision.—Dr. Torek said that he has treated eight cases of diffuse peritonitis, all of which recovered, though he used the old barbarous method of a long incision, one of the incisions reaching from the ensiform to the pubis. Lavage was done very thoroughly by pouring water from pitchers directly into the widely opened abdominal cavity and the intestines are thoroughly washed off with the hand. No drainage, not even a small cigarette drain is employed after the operation and the wound is closed immediately and completely. Three cases recovered with primary reunion. Three had suppurating stitch wounds in the track of the through-and-through silk sutures which he employs. These subsided after reunion of the edges of the incision layer by layer. There was one intramural abscess and one intraperitoneal abscess, though this occurred near the umbilicus on the left side, far removed from the original focus of infection, to which, if anywhere drainage would have been thought necessary. These cases were done twenty-six to fifty-four hours after the beginning of peritonitis, though Dr. Torek considers that after forty-eight hours the prognosis is very poor.

Variations in Virulence.—Dr. Berg said that all purulent exudates are not of the same nature nor as virulent. Some cases of purulent peritonitis with intensely fetid pus all over the peritoneum will get better if the original focus of infection be removed. At times, the morning after the operation such patients will be reading the paper. Other patients that seem much less seriously affected do not improve but may even prove to be fatally affected. Hence the necessity for demanding what is purulent peritonitis. Whenever the peritoneum is shiny, its absorbent power remains. Whenever it is dark and sodden, it does not allow absorption and simply furnishes a culture medium for micro-organisms. It not infrequently happens in cases where peritonitis has been the consequence of typhoid perforation or of the perforation of a gastric ulcer that the septic material in the abdominal cavity comes in contact with the wound margins and infects them, causing serious septic or even gangrenous processes. Great care should be exercised then for the protection of the edges of the wound and drainage should be employed. Riegel showed that in animals death might be produced from the shock of injections of normal salt solution into the peritoneal cavity. Even lavage then may be contra-indicated. If the peritoneum is to be trusted, it must be trusted completely.

Dr. Blake, in closing the discussion, said that the present tendency is to use ever less and less drainage. Septic material must be removed from the abdominal cavity, especially such substances as bile and food material from the stomach, but very little manipulation must be allowed. If the peritoneum is shiny it can be depended on to take care of itself. Superficial drainage is all that is necessary in most cases.

THE OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, held Thursday, May 5, 1904.

The President, R. C. Norris, M.D., in the Chair.

Rupture of the Uterus, with a Critical Review of Fifty Cases from the Standpoint of Treatment.—This was the paper of Dr. W. A. Newman Dorland. He said rupture of the parturient canal at any point is an accident of labor, and more rarely of pregnancy and the puerperium, which is associated with more or less danger to the patient, either immediately from hemorrhage and shock, subsequently from sepsis and peritonitis and more remotely from its tendency to the ultimate development of prolapse of the pelvic viscera. The rupture may occur in the uterine wall from the fundus to the internal os; it may consist merely in a tear limited to the cervical tissues, or extending outward from the neck into the vaginal vaults and pelvic connective tissue; it may occur in the vaginal wall with or without the development of a pelvic hematoma; or it may take place in the perineal tissues during the delivery of the head through the vulvar ring. The most serious form is that occurring in the womb itself. This may develop spontaneously, but more frequently is traumatic in origin. It is an extremely rare accident, occurring about once in 4,000 cases of labor. During the past three years (1901-3) there have been recorded in the world's literature 49 cases of uterine rupture, the case reported in this paper completing the even half hundred. Twelve of these cases resulted fatally, giving a mortality of 24 per cent. Three of the patients died of hemorrhage or shock before any course of treatment could be instituted. Sixteen of the women were treated expectantly—that is, with uterine and vaginal tamponade and drainage—and of these four perished (a mortality of 25 per cent.) greater, as will be noticed, than the total mortality for the fifty cases. Thirty-one of the patients were treated by operation, either suturation of the uterine wall, the Porro operation, or total extirpation of the uterus, and of these cases five died. This yielded a mortality of 16$^{1}/_{31}$ per cent. The great superiority of the operative course of treatment according to the modern technic is evident from this showing.

An examination of the records as condensed in the table accompanying this paper, will throw some doubt upon the accuracy of the diagnosis in a few of the cases. The symptoms manifested might have resulted from the development of a broad ligament hematoma or other variety of puerperal hematoma. Such cases would recover naturally in most instances under the expectant course of treatment instituted. Again, of the sixteen cases treated expectantly, seven, or 43¾ per cent, showed an incomplete tear of the uterine

wall, while of the operative cases only one showed a rupture of this nature. All of these eight cases recovered. Of the nine cases of complete laceration of the uterine wall treated by tamponade and drainage, four, or 44.4 per cent., perished. It we compare this with the thirty cases of complete rupture with five deaths—a mortality of 16⅔ per cent.—the inference must be obvious.

The conclusions to be drawn from this brief study are as follows: Incomplete lacertions of the uterine wall, if the hemorrhage be moderate and the diagnosis accurate, may be well treated by careful vaginal and intra-uterine tamponade and an expectant course of treatment. Complete lacerations, the peritoneal cavity being opened should, under unfavorable circumstances, such as uncleanliness of locality and lack of surgical appliances, be temporarily treated by intra-uterine tamponade and the administration of astringents and stimulants; the patient should then, if possible, be conveyed to some hospital and the abdominal cavity opened. Under favorable circumstances the abdomen should be opened as speedily as possible and the rupture in the ulterine wall sutured in suitable cases, or a Porro operation or a total extirpation be performed, according to the nature of the case.

Dr. L. J. Hammond, in the discussion, said: It may be of interest to refer to the case which, while not under his care at the time, has become familiar to him by reason of the records having since been placed at his disposal. The woman was thirty-five years of age and was brought to the lying-in institution in active labor on the morning of July 7, 1902, with labor apparently progressing favorably according to the record, until 8 P.M. the same day, when she suddenly screamed from an acute pain in the lower abdomen and at once the woman's condition was apparent to the nurse as something out of the usual. The pulse suddenly went to 140 and was very weak and thready. At 1.30 A.M. the pulse was so weak and thready that it was impossible to count it and contractions had about ceased. The physician then undertook to deliver by forceps, and for reasons not stated in the record the forceps were abandoned and version undertaken. The woman dying, however, before delivery was completed. The autopsy made a few hours after death was confined to an examination of the abdominal contents only. This cavity was filled with large quantities of liquid and clotted blood, generally disseminated throughout the intestines. There were also firm adhesions between the abdominal viscera. The uterus was about the size of a child's head. There was a rupture of the anterior wall of the vagina which extended into and communicated with the peritoneal cavity. The cellular tissue between the bladder and uterus seemed to have been torn away, and the vesico-uterine ligament was torn and the uterine muscle laterally denuded of its peritoneal covering for some distance. This was regarded as the source of tremendous hemorrhage within the abdominal cavity. Dr. Hammond thinks this case would confirm the position taken by Dr. Dorland that operative interference is alone, and at once to be employed in cases of this kind. Personally Dr. Hammond has had no experience in dealing with ruptures of the uterus, except in partial ruptures, as seen in extra-uterine pregnancies, but concluded this from general surgical principles.

Dr. Daniel Longaker said he regretted that he did not hear all of Dr. Dorland's paper. He had seen one case of rupture of the uterus. This was about twenty-five years ago, in his very first case of labor. He had a very distinct recollection of the regularity and severity of the pain which came to a certain climax when the woman screamed violently, and accused him of having killed her. Of course, he had done nothing, beyond observing the course of an impossible labor. It was fortunate that some of his chiefs came to his assistance, or he might have fared as badly as the woman herself. She was a large Irish woman, giving birth to her ninth child. The child escaped into the abdominal cavity and the woman died four or five hours afterward, undelivered. The surroundings, of course, were very poor and miserable. Dr. Longaker was only a student, and none of those whom he called, seemed to have sufficient courage to deliver the case. The next case of rupture of the uterus which he has knowledge of, occurred in the practice of a midwife, who some years ago was in the habit of sending for him in her difficult cases. The child was already delivered when he reached the house, and the woman was in shock, suffering from hemorrhage, the placenta being undelivered. He passed his hand into the uterus, delivering the placenta, and passed it into the peritoneal cavity and grasped bowel. That patient died very promptly. The third case which Dr. Longaker saw was in an impossible labor in which several attempts had been made to secure delivery by forceps, the child's head being arrested above the brim. The woman was giving birth to her first child. He found her in profound shock, pulseless and with an exsanguine look. The uterus was ruptured from the vaginal juncture and well up into the body. The fetus had not escaped entirely from the cavity. Delivery was made on a dying woman. He has not seen rupture of the uterus in any case where version was either made or unsuccessfully attempted. He shall probably have a little more to say on this subject in his paper.

Dr. Stricker Coles said: In a case in which he had been asked to repair the lacerations, on making an examination he found the intestines were in the opening. A douche of bichloride had been given the night before. He found more than ordinary abdominal distention and the woman was in a bad condition. After finding a rupture in the peritoneal cavity, he hardly knew what to do. She would not stand being removed to a hospital. He therefore put in a glass drainage tube and washed out the wound with salt solution, but the woman perished soon afterward. The next case was a multiparous patient in her fifth pregnancy. It was a case of hydrocephalus. There was breech presentation and the head was impacted. The case was delivered with great difficulty and craniotomy had to be done on the aftercoming head. Making an examination for lacerations, he found a tear in the peritoneal cavity. The patient had just been up for four or five days from a bad case of typhoid fever. The result of the laceration was so severe that in her weak condition she perished soon after delivery. In both of these cases abdominal section might have saved them if they had been seen earlier.

Dr. L. J. Hammond said he would like to add a part of the history of the case not at first referred to, which is important. The first labor was a very difficult one necessitating instrumental delivery, then followed this labor and extensive bilateral laceration. The second pregnancy she aborted at the fifth month, and following this abortion there was a very protracted recovery, due, from the history of the case, to the presence of extensive peritonitis. He mentions this because Dr. Dorland has said that many cases show cicatricial conditions of the uterus to have previously existed. As a matter of fact, the cicatrices from these lacerations were not at the point of rupture, it being, as before stated, along the anterior wall or roof of the canal and seemed to bear no relation to this weakened area.

Dr. George M. Boyd said he did not hear all of the paper, but the review of the fifty cases is, he thinks, of a great deal of interest, particularly because of the rarity of rupture of the uterus. It has been his good fortune never to have seen a case of so-called complete spontaneous rupture of the uterus. He has had a number of cases of incomplete rupture, particularly of the lower segment extending into the broad ligament, and he remembers one case of traumatic tear through the fundus from the use of placental forceps. Incomplete rupture of the uterus is probably more frequent than one realizes. It seemed to him that with the symptoms of hemorrhage the course to follow would be to make a careful exploration of the uterus, and determine whether the tear is complete or incomplete. If it is complete immediate section and repair of the injury should be done by laparotomy. If the tear is not complete, it should be treated by tamponing the uterus. Some operators fear rupture of the uterus after celiohysterectomy. In the cases he has seen there seemed to be no tendency to rupture in second pregnancies.

Dr. Dorland, in closing, said he would like to thank the gentlemen for the most interesting discussion given to his paper. In the table accompanying the paper which he had read, a study of the clinical features of the cases reported shows some very interesting points, some of which have been touched upon in the discussion. For instance, the frequency of multiparity in this accident is well shown. In the 50 cases reported there were 24 of the women who were in their fourth pregnancy or over, one being in her twelfth gestation. Thus, almost half of the cases showed advanced multiparity, and this may have had something to do with the development of the rupture. In the record of the cases reported in the discussion he noticed that nearly all—if not all—occurred in private practice, and almost all resulted fatally. The statistics reported by Schmidt and others, come largely from hospitals, and Dr. Dorland firmly believes that if the obstetrician were to collect a similar series of cases, all occurring in private practice, the mortality would be almost absolute. Another feature noted in his table is the large percentage of pathological obstetric conditions, such as hydrocephalus and breech presentations, and cases associated with degenerated muscle-tissues, which was probably the condition in the case mentioned by Dr. Coles. Again, the frequency of incomplete rupture must be much beyond the actual showing of records. He recalls reading somewhere the statement made by some abdominal surgeon that interstitial pregnancy existed much more frequently than now thought, and that it no doubt ruptured frequently into the uterine cavity, giving the symptoms only of an abortion without any indication of the occurence of an incomplete uterine rupture, which, in reality, does exist.

Version in Delayed or Obstructed Labor.—Dr. Daniel Longaker read this paper. By the exercise of great care, under complete etherization version is usually feasible in transverse presentations even though ergot had been given and an arm has been prolapsed for some time. Celiohysterectomy is, however, indicated in the presence of actual or impending rupture of the uterus. Version is of special value in cases of incipient transverse presentation. Should all expedients fail to secure engagement and descent of the head, and speedy, natural or instrumental termination of the case, which has often dragged along many hours beyond the normal duration, version is often capable of yielding brilliant results. In cases of simple flat pelvis, with direct conjugate not under 7.5 cm. or 8 cm. version is indicated, if the conditions for successful employment of the forceps be lacking. It is not a rival of the forceps at all, but it finds its legitimate place as a supplementary measure in the treatment of relative pelvic contraction. An earnest protest is made against the routine use of the forceps. Such practice leads to bad results to both mother and child. Where the head is arrested above the brim application of the forceps is a procedure of questionable expediency, quite difficult in the absence of relative contraction, while in its presence, it had better not be undertaken. A strong plea is made for the accurate determination of the relation of the fetus to the pelvic canal by inspection and palpation—external examination. Estimating the location, size and compressibility of the head from the outside and above the pelvic brim rather than from below and within, exclusively, as is the too uniform rule. This rigid plan of examination must antedate labor, especially in primiparæ, for six or eight weeks, if uniformly satisfactory results would be attained.

Dr. R. C. Norris, in the discussion, said many of the profession remember reading the former earnest discussions on this subject by Goodell and Ellwood Wilson in this hall. This Society now comprises a new generation of obstetricians, and for one's own satisfaction one must thrash out this subject. It is one full of interest, and Dr. Norris trusts it will have a generous discussion. The Society shall be glad to hear from those present who have clear-cut ideas to express or experiences of this type of case to relate.

Dr. Oliver Hopkinson said: In treating these so-called border-line cases one encounters many difficulties. He thinks the profession should be guided by the position of the head. If a floating head, version is the easier operation of the two and more safe for the mother. If impacted or partly engaged, he would make an attempt at forceps delivery first. He was very much interested in Dr. Longaker's reference to his case of impacted transverse presentation. With the child lying transversely, with the shoulder or arm impacted, it is almost impossible to get the hand around and grasp the foot, but gently working the hand around and grasping the pelvis, and pushing up the head, the obstetrician will succeed in getting the pelvis of the child at the superior strait. Dr. Norris remembers one case he saw in consultation, in which the membranes had drained for a number of hours. The man had attempted to do version, and was unable to reach a foot. The back was anterior, as it usually is in these cases, and it was rather easy for him to pull down the pelvis of the child. He did what might be called pelvic version instead of podalic version. Dr. Norris feels that further attempting to do a podalic version might have ruptured the uterus.

Dr. Stricker Coles said he thought the treatment of these cases in which the arm is prolapsed and the back anterior were not very difficult. In nine cases reported he had little difficulty, because the back can be made to revolve along the anterior abdominal wall and the breech can easily be brought down. If the back is behind and impacted under the promontory of the sacrum, to do version you must shove the entire child up. Attempts at version in such a case is a great mistake, and one is almost sure to rupture the uterus. When the arm has been outside for some time, and is gangrenous, there is only one thing to do—to amputate. After that is done the best thing to do is to decapitate, or decapitate before and deliver the child without any attempt at replacement or version. Dr. Coles said he had very distinct ideas in which cases he would employ version and in which forceps. If he can get the head to engage, he noted carefully the amount of difference

there is between the child's head and the mother's pelvis. If he can put the mother in Walcher's position, and bring the head to engage, he uses the forceps; but, if he cannot get the head to engage, and as he pushes it down he can feel it resting over the promontory of the sacrum on one side, and the symphysis on the other, showing that the head is larger than the pelvis, he would be careful. If there is a slight difference, version is the operation to be done. When you find a large disproportion, Cæsarean section, symphyseotomy, or some other form of operation, should be done. You must measure the pelvis, and estimate the size of the head. He tries to estimate this by fitting the child's head to the mother's pelvis, and on his results in this he bases his treatment. If he can make the head engage, he feels that there is very little difference, and he uses the forceps. Version is a splendid operation, but should not be employed too generally in contracted pelvis, without carefully studying the case.

Dr. George M. Boyd said it is timely that the subject of version was discussed, and particularly version in contracted pelvis. It must be remembered, however, that the profession has made considerable progress in the last decade or two, and that other operative interference has come to our aid. In the days of those celebrated teachers, symphyseotomy and Cæsarean section were not so much considered. He would employ version for transverse presentation, and occasionally, for flat pelvis; but he would consider it a makeshift operation in contracted pelvis. It must be remembered that a fetal mortality of 30 per cent. in breech presentation is on record. Failing with forceps in a generally contracted pelvis, it seemed to him it is better to do craniotomy than to turn, particularly if the forceps had been used faithfully.

Dr. J. S. Raudenbush said that last fall, in a primiparous case, twenty-five years of age, the internal conjugate normal, external conjugate 20.25 cm., the woman started into labor in the morning, and had strong, vigorous pains. She had always been a strong, healthy woman. The head would not flex sufficiently to pass down in the pelvic canal. Between 10 and 11 at night the membranes ruptured, but the head remained in the same position. The anterior fontanelle stayed entirely too low, and he decided that the condition demanded the application of the forceps. These, however, failed and he saw that he could not complete flexion so that the head could come down as it should. The membranes had been ruptured for two hours, and he did not know whether he might not succeed in version, since he could not produce complete flexion. He succeeded in getting the head up out of the pelvis and had sufficient liquor amnii to do version and he delivered a living child. A week later he attended a multiparous woman, a sister of the former patient, and found the head in exactly the same position. Within an hour complete flexion commenced to come on, and there was a normal delivery within three hours of his arrival. The next case occurred within a month in a primiparous woman about twenty-two years of age. Her measurements were practically normal. The external conjugate was 21 cm. and he anticipated no trouble. The woman was a neurotic case, the pains were weak. There was a left occipito-anterior presentation, but the head would not come down. He applied the Simpson forceps and afterward the Tarnier and delivered the child, but it was born dead. He has since regretted that he did not do version two hours earlier when the head was high in the pelvis and the membranes unruptured. About three weeks ago, at the Medico-Chirurgical Hospital, a colored woman with diminished measurements of the pelvis fell in labor. Later in the day the conditions were about the same, there was but little dilatation and the head was in about the same position. He waited until after six o'clock, when he made another examination, having determined upon version; but by that time the head had commenced to flex completely. It was a left occipito-anterior position and there was a beginning of cervical dilatation. He left the case in the hands of the resident. At about 10 o'clock in the evening the case was normally delivered. This case shows that even with diminished measurements neither forceps nor version were necessary.

Dr. R. C. Norris said he had listened with great deal of interest to this discussion, and he thinks it may be taken for granted that in the lesser degrees of pelvic contraction, the mortality for the child is greater following version than the skilful application of the forceps. On the other hand, version is much easier to do than a skilful forceps operation, so that he believes for the man of average obstetric experience, version is the better operation for him to perform. A man with wide experience with axis traction forceps becomes very skilful in their use and will save more babies if he resorts to the forceps. The rapid extraction of an infant's head through a moderately contracted pelvis after version means a sudden compression of the child's head which, in his experience and so far as his reading goes, is more dangerous to the child than the gradual compression as applied with the forceps. In other words, the baby, as it passes through the birth canal head first, has its head gradually moulded and compressed in every step of the labor. He recollects the advice given him many years ago by Dr. Godell, that in cases with a moderate degree of contraction, when the use of the forceps had been decided upon, the operator should not be in too great haste to extract the child through the pelvis. Dr. Norris has learned the value of that in his practice he says. He has put on the Tarnier forceps and made traction and secured some advance of the head. He has taken them off, gone to his room and slept for half an hour, having the nurse call him, when he would put the forceps on again and get a little further advance of the head, to be again followed by removal of the forceps. In this way he feels that he has saved more babies with the forceps than would be possible by version. A practical point is the determination, as Dr. Boyd has said, when it is or is not justifiable to use forceps or version. That is one of the most difficult problems for even the expert obstetrician. The question depends more upon an individual's specially trained knowledge and experience than any other problem of obstetrics. His practice leans toward the least aggressive means of treating these cases, although he takes as much pleasure as any one in doing Cæsarean section. He can only refer to his work at the Preston Retreat. He is preparing a paper embracing some twenty-five cases of induced labor for minor degrees of pelvic contraction. In one of these cases he anticipated especial difficulty and grave risk for the child from induced labor. The woman was therefore allowed to go to term and was prepared for Cæsarean section, but was treated as if she were a private patient in her own home. She was allowed to go into active labor to test Nature's efforts and delivered herself spontaneously, thus saving the Retreat the record of never having had a Cæsarean section in two thousand labor cases. He believes the selection of treatment is a matter of individual opinion and experience, and he thinks the determination of when to employ forceps, when to do version, or when Cæsarean section must be done is one of the most per-

plexing problems in obstetrics to-day. The method to aid such a choice he has found most satisfactory is, after a few hours of actual bearing-down pains, to study the distance between the promontory of the sacrum and the sagittal suture, as the head lies transverse in the pelvis. The degree of lateral flexion and the distance between the sagittal suture and the promontory indicate fairly well the relative disproportion between head and pelvis. A distance of two or more centimeters favors the use of the forceps. This has guided him sufficiently to avoid doing Cæsarean section on several occasions. The woman must be examined under ether. He agrees with Dr. Boyd, that if forceps are used first and they fail and version follows, few babies would be delivered alive. The physician should make up his mind before he starts to operate which he must do, and then proceed. If he finds that he has made an error of judgment and cannot without undue violence get the head well engaged in the pelvis, he should either turn the case over to someone else; or, if he is a skilled abdominal operator, he should open the abdomen.

He confesses that when he learned the records of pelvic deformity managed by the average practitioner and sees how frequently disastrous instrumental deliveries occur, he believes that forceps are resorted to prematurely and in a violent manner. If moulding and adaptation of the head were permitted to occur or were carefully obtained by gradual compression and traction with axis-traction forceps there would be less injury to the child than is likely to follow rapid extraction after version.

Dr. Longaker, in closing the discussion, said he wanted to thank the gentlemen for participating in this discussion. It is a large and interesting question and one which cannot by any means be exhausted in a single paper. He thinks nothing has been said with which he disagrees. He certainly agrees most fully with the opinion that after an attempt at forceps with failure, resort to version is improper. He does not remember ever having been guilty of such poor judgment. As said in his paper, it seems to him that these two operations can hardly be called rivals. Where the indications for a successful forceps delivery exist, there the indications for a version do not exist, and the converse of this statement is just as true. He would say to Dr. Hopkinson in regard to doing a breech version that he thinks in these cases he has accomplished a great deal with the hand outside. You can pass the hand well down into the flank toward the back and as the uterus has adapted itself so nicely to the fetal outline, you can locate the leg and push it down from the outside so that the deep introduction of the hand into the uterus is not necessary.

In regard to cases alluded to by Dr. Coles, in which there was present a condition of putridity, it is, of course, good practice not to return such an arm. The question of doing hysterectomy would come up in a case so long neglected, and in which there would certainly be infection. In the case in which an arm had been prolapsed for twelve hours, he expected to find such firm impaction that version would be impossible and went prepared to do embryotomy. It is a simple thing to imitate that which occurs under the natural forces of labor—spontaneous involution. It would not be a difficult thing to open the thorax, eviscerate the child and allow it to double up in the pelvis and thus simulate the process of spontaneous evolution. He agrees with Dr. Boyd in the inadvisability of resorting to version after the forceps have been employed. In regard to Tarnier's forceps, he is in the habit of using it in high application, but is not enthusiastic about the results where there is any decided degree of contraction to be overcome. He agrees most thoroughly with the views of the President regarding the expediency of inducing premature labor. He has had several cases during the past winter, in which the results have been all that one could desire. The last case was an obliquely contracted pelvis due to coxalgia in childhood. The woman fell into his hands in her first pregnancy and the degree of contraction was estimated. She accepted the advice to have labor induced in the thirty-second week, and gave birth to a fine infant weighing a little under seven pounds and the child continues to be a perfect specimen. In her second labor a few months ago the same plan was followed and delivery was remarkably easy. The induction of labor in the second case was the easiest thing possible. The woman received a number of douches by way of preparation, and at about four o'clock in the afternoon Dr. Longaker began the active procedure of the induction of labor, consisting in the introduction of a small McLean bag. Both sides were dilated at once and in about half an hour she expelled the bag, and before the nurse could call the Resident, four hours later, the baby was born and has done well. There is no question as to the advisability of this operation.

BRITISH MEDICAL ASSOCIATION.

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

(Continued from Page 569.)

Section on Tropical Medicine.

Human Trypanosomiasis and its Relation to Congo Sleeping Sickness.—Drs. Christy, Dutton and Todd gave a report of the Liverpool School of Tropical Medicine. The expedition arrived at Leopoldville on November 21, 1903. Two of its members who had made a short tour through the cataract region arrived a week later. During their journey through this district, in which Congo sleeping sickness was said to be extremely prevalent, many cases, with very anomalous symptoms, but called sleeping sickness, were seen. As already stated in a first progress report, trypanosomes were found in the peripheral blood of some of these cases. It therefore became necessary to commence a clinical study of human trypanosomiasis in order to see what relation it bore to Congo sleeping sickness. Leopoldville offered particular advantages for such a study, and the members of the expedition decided to remain there for a few months. A large bungalow was placed at their disposal by the Congo Government, and, through the kindness of Dr. Grenade, the State Medical Officer, and Dr. Broden, Director of the Leopoldville Bacteriological Institute, the patients at the native hospital, a good proportion of whom were infected with trypanosomes, were given to the expedition to study. In addition to this, the presence of about 2,000 State employees—laborers, soldiers, etc.—afforded an easily-accessible healthy native population. Later, the hospital for natives was found unsuited for a complete examination of the cases, and a new structure was built, and supplied with the necessary appurtenances through the kindness of the local government. The members of the expedition have therefore for four months been in a position to keep patients under continued and careful observation. Out of a total of 465 natives, coming from all parts of the Upper Congo, as well as the districts round Leopoldville, where they were examined, 54 were found to have trypanosomes in their blood, and out of 707 examined at Boma, Matadi,

and in the Cataract Region of the Lower Congo, 49 were found to be infected with them.

In the British Colony of the Gambia only six cases of human trypanosomiasis were found among 1,043 natives. These Gambia cases presented no definite symptoms of illness, and nothing abnormal was detected, with the possible exception of an occasional rise in temperature and increase of pulse frequency. In the Congo we have also seen examples of the mild Gambian type, but the majority of our cases have shown marked symptoms of illness. From a close study of the Congo cases, it becomes evident to us that there is no well-defined line of demarcation between these two forms of the disease, though, for descriptive purposes, we here propose to consider them under three main headings, A, B, and C.

Type A. Cases with no definite symptoms of illness.

Type B. Cases with few symptoms.

Type C. Fatal cases showing well marked symptoms, the most notable being fever, lassitude, weakness and wasting.

It is significant to note that a large percentage—36 out of 44—of those classes under types B and C were believed by their friends to be suffering from "sleeping sickness."

We have seen cases coming under type C, in which no sleep symptoms were ever present, as well as cases in which some of the classical symptoms of sleeping sickness were noted. We therefore subdivide type C into: 1. Fatal cases showing no sleep symptoms. 2. Fatal cases showing sleep symptoms.

Here again no sharp division is possible between these two groups, still, we think it not inadvisable to separate them, since from our experience here, we believe that altogether too much prominence, as a diagnostic feature, has been given to what appears to us to be only a minor and inconstant feature of this disease, namely, sleep. The prominence given to this system has tended to disguise the true nature of Congo sickness which is, primarily at least, a trypanosome infection.

Trypanosoma Gambiense as Cause of Congo (Sleeping) Sickness.—(*a*) As already indicated, in nearly every case in which sleeping sickness was diagnosed or suspected, trypanosomes have been found in either blood, cerebrospinal fluid or both. (*b*) We have shown that there is a very evident clinical connection between those cases which have only very light symptoms (trypanosoma fever) and the advanced cases of "sleeping sickness" seen in hospital. (*c*) In Gambia there is an undoubted trypanosoma disease in horses which is characterized, in its first stage, by the absence of obvious symptoms; and later by fever, emaciation and weakness. The course of this disease may be chronic and death delayed for a long period. (*d*) The sleeping sickness of the Congo is known to have a long latent period. Symptoms are said to have been developed in some cases two to five years after having left an infected locality. It is interesting to note that natives may be infected with trypanosomes for many months without showing signs of illness. (*e*) Europeans infected with *Trypanosoma gambiense* show symptoms which are quite comparable to those observed in uncomplicated trypanosome infections of Congo natives. (*f*) In Gambia, where cases of sleeping sickness are rarely seen (Dr. R. M. Forde, Principal Medical Officer of Bathurst, stated that perhaps one case a year came under his care), only six out of 1,000 odd natives were found to be infected, by the examination of fresh cover-slip preparations. In an almost exactly equal number of a similar class of natives examined in the same way in the Congo, 46 have been infected. In Uganda, where the disease occurred in epidemic form, the percentage of infection among the general population was still higher. *Duration.*—It has been impossible to decide for how long a period a native may be infected with trypanosomes and still show no definite signs of disease. One man already mentioned is known to have been infected for over a year and is still perfectly well. It would appear from one or two early cases which have been observed that the transition from this "latent" stage to one in which symptoms are noticed may be very gradual. We have only observed eight fatal cases of Congo sickness in which the necropsies showed no obvious secondary infection. The duration of the disease dating from the recognition, either by the friends of the patient or by ourselves, of obvious signs of ill-health, has been two to four months. *Recovery.*—In our experience no native who has shown definite and constant signs of ill-health has recovered. The trypanosomes were found by Dr. Broden on February 7, 1903, during an attack of fever which lasted for a few days. During the last year Dr. Broden has seen no parasites in the blood.

Death.—We do not think that we have sufficient evidence to state that death is produced by the trypanosomes alone. Secondary bacterial infections seem to determine the fatal issue of many cases of Congo sleeping sickness. Thirteen out of twenty-two necropsies performed at Leopoldville showed complications or obvious secondary infections. They were as follows: Purulent meningitis, 4; purulent pleurisy and pneumonia, 1; pneumonia and localized tubercle of lung, 1; localized gangrene of lung, 1; enlarged caseating and breaking down glands in thorax and abdomen. No tuberculosis lesions in organs. (Tubercle bacillus in glands seen in one case), 2; dysenteric ulceration of large bowel (perforation in one case), 2; universal adherent pericardium (recent), 1; infiltration of pus in femoral, inguinal, and intestinal iliac glands (gonorrhea), 1. According to the post-mortem reports of Colonel D. Bruce and Dr. Nabarro very similar lesions were observed in Uganda, where 10 out of 20 necropsies on sleeping sickness patients showed obvious secondary infections, and in three instances purulent meningitis. It will be noted that purulent meningitis has been the most frequent complication both in Uganda and in the Congo. The brain in these cases presents a very abnormal appearance. The convolutions, especially on the upper surface, are covered and glued together by a thick layer of tenacious lymph, and the vessels of the pia arachnoid are intensely congested.

It is evident that such morbid changes are explicable on bacteriological grounds, and we have found microscopically in all such cases an almost pure culture of a diplococcus occurring in small chains. These observations make us doubt whether the acute congestion of cerebral vessels, accompanied by an increase of pia arachnoid fluid containing pus cells, seen by us here, and described by others, as typical of sleeping sickness can be attributed except indirectly to the trypanosome. The Portuguese Sleeping Sickness Commission, Dr. Broden in Leopoldville, and Dr. Castellani in Uganda, have all described bacterial infections in a very large percentage of sleeping sickness cases examined before as well as after death. It must be noted that such purulent changes have not been described in animals dying from trypanosome infections.

MULFORD'S ANTITOXIN
Every Dose Furnished in this Aseptic Glass Syringe Ready for Instant Use. No Advance in Price.
MULFORD'S ANTITOXIN
"SAVES MOST LIVES"

Mulford's Antitoxin

"SAVES MOST LIVES"

You know Mulford's Antitoxin—what it has done and can be depended upon to do; and you know how surely imitations fall short of the original, because they haven't the creative spirit behind them that makes standards.

You know how we have stood, from the beginning, for better, and surer, and safer Antitoxin and methods of using it.

So, whenever an imitation of Mulford's Antitoxin and Syringe is offered, ask yourself: Will it do the work as surely? Is it thoroughly aseptic? Is an imitation ever as good as the original?

"Your Antitoxin gives quick results and your Serum-Syringe overcomes ever difficulty in administration. It is the best device ever offered for giving Antitoxin."

FACTS

1. We were the first American firm to prepare a reliable Diphtheria Antitoxin.
2. We were the first to offer Antitoxin of a high unit strength.
3. We first protected absolutely the strength and efficiency of Antitoxin by dating each package, ensuring a reliable product.
4. We originated the standardization of Antitoxin, so that each cubic centimeter of Antitoxin contained a fixed and definite number of Antitoxin units.
5. We devised the first serum-syringe package for administering Antitoxin. Our Aseptic Glass Syringe was introduced in 1902, and has overcome every obstacle for the easy and prompt administration of Antitoxin. Air never comes in contact with the serum, nor is it possible to inject air into the patient.

Every advance in the scientific production and method of administration of Antitoxin has been originated by us. We are the largest producers in the world.

To Secure the Best Results, Specify Mulford's Antitoxin. It **"Saves Most Lives"**

"I wish to congratulate you upon your Syringe for administering Antitoxin Your ntitoxin excels all, not only in quality, but for convenience in administration."

RESULTS

IN THE MINNEAPOLIS CITY HOSPITAL

[EXCERPT FROM 1902 REPORT]

"We have had during the year (ending December 31, 1902) 170 cases of diphtheria with two deaths; these being in a moribund condition when brought in the hospital. Such results have been obtained by a very liberal use of Antitoxin.

"We believe it is economy to be liberal in the use of Antitoxin, as the disease is thereby shortened—the saving of life is, however, the best reason." In this entire series of cases Mulford's Antitoxin was used exclusively.

All Reports Prove that it **"Saves Most Lives"**

"I am more than pleased with your Aseptic Syringe package. It works perfectl
and is the only practical syringe on the market for the administration of Antitoxin."

10,000 Satisfactory Vaccinations

SWIFT & COMPANY — SURGEON'S OFFICE

H. K. MULFORD CO., Chemists — Chicago, Ill., March 28.

DEAR SIRS:—It affords me great pleasure in reporting to you the outcome of our last vaccination at the Union Stock Yards.

We vaccinated, with your glycerinized lymph, about 4000 people, young and old, with the best results. Ninety-eight per cent of "takes" were observed, with but twelve or fourteen cases reported which had badly swollen arms. These, however, can be accounted for as due to infection during the work in the Packing Houses after vaccination. This makes **10,000 people vaccinated with your lymph within the last two years with the best results known,** and for that reason your lymph cannot be too highly recommended.

Yours truly, R. H. VON KOTSCH, M.D.,
Surgeon-in-charge Swift & Co. and Libby, McNeill & Libby

The Best Record Ever Made

"Within the past month I have vaccinated 576 patients without a single failure, nd with no excessively sore arms. I vaccinate without drawing blood and treat

Periodicity and Frequency of Occurrence in the Peripheral Blood.—Frequent examinations of the finger blood of trypanosome cases has shown that the parasites may, to the ordinary methods of examination, be absent from the peripheral blood for varying periods. The frequency with which the parasite is obviously present in the peripheral blood bears no relation to the severity of the symptoms.

Number of Parasites Appearing in the Blood.—The number of parasites seen in ordinary fresh cover-slip preparations is generally small, but in some patients very large numbers have been recorded. In two cases a large increase has occurred during the few days immediately preceding death.

Symptoms Associated with Parasites in Blood.—From our observations we cannot make out any definite relation between the temperature and pulse and the appearance of the parasites in the peripheral circulation. A rise of temperature is not necessarily associated with an increase of parasites in the blood. It appears, therefore, that the number or constant presence of the parasites in the peripheral blood bears no relation to the severity of the disease. As a rule, we have found that the parasites occur in extremely scanty numbers in the cerebrospinal fluid, seldom more than 1 to 3 or 4, very occasionally from 10 to 20 to the cover-glass preparation of the sediment left after centrifuging. As already stated, neither at Leopoldville nor anywhere on the Lower Congo, up to the present time have we met with a case of Congo sickness in which sleep has had a prominent place among the clinical symptoms, and in those few cases in which it has been noted a few days before death, or at irregular intervals during the course of the disease, it has not been describable as a deep or continuous sleep, but merely a drowsy or somnolent condition from which the patient was at once aroused by being touched, or perhaps, by being spoken to. On comparing the cases in which parasites were found in the cerebrospinal fluid with those in which they were not found, we see that most of the few cases in which drowsiness was a feature, together with cases in which head symptoms, for example, mild mania, epileptic attacks, flexeur contractions, and convulsive seizures were conspicuous are upon the plus side. On the minus side similar cases are also found, but it is noticeable that there are many of those cases which showed hardly any symptoms, and which, if no fatal complications intervened, lived on month after month in an advanced state of emaciation, retaining their faculties, speech and appetite, etc., almost to the moment of their death. It is therefore not improbable that the presence of the parasites in the cerebrospinal fluid at a late stage in the disease may tend to increase the gravity of the case by predisposing to one or other of many complications, or in other ways hasten a fatal termination; but that this is not invariably so is proved by at least two of our cases, one of whom is the most sturdy patient under observation. No animals inoculated with material in which trypanosomes were seen taken post mortem from cases of trypanosomiasis have ever become infected. Parasites have been seen in the peripheral blood of infected animals only at more or less irregular intervals. Guinea-pigs have perhaps shown themselves the most satisfactory of ordinary laboratory animals, since, as a rule, when once infected parasites are constantly present in large numbers. Death, in the small number of our infected animals which have died, can in no instance be certainly said to have been due to the trypanosome alone. These are all points in which the Congo trypanosome resembles *Trypanosoma gambiense*. In addition, the "incubation period," that is the period intervening between the inoculation of small or medium doses of infective material, and the detection of the parasite in the peripheral blood of the experimental animals, is much the same for both parasites.

	Congo Trypanosome.	Trypanosoma Gambiense.
Rats	5 to 20	7 to 20
Mice	5 to 16	6 to 7
Rabbits	17 to 27	21
Guinea-pigs	11 to 25	12 to 21

Monkeys of two different varieties, both belonging to the subfamily *Cercopithecus*, have been infected. Only one has shown slight symptoms of ill health. On two occasions a slight rise in temperature and loss of vivacity has accompanied one of the irregularly appearing intervals during which parasites have been seen in the peripheral blood. This monkey has been infected for nearly three months. We have again failed, even with large doses of blood containing huge numbers of trypanosomes, to infect two dog-faced monkeys (*Cynocephalus*).

Transmission Experiments.—We have attempted to repeat the transmission experiments made by Bruce, in Uganda, with the tsetse fly. These flies are rather numerous in the bush along the river banks on either side of Leopoldville, and a fair number are daily brought to the laboratory by a gang of boys supplied for the purpose by the local authorities. Practically all the flies brought in by them have been *Glossina palpalis* (native name, "mavekwa"). Two specimens of *Glossina fusca* have been brought in during the past four months. Unfortunately we have had the greatest difficulty in obtaining monkeys, and have only been able to use two for these experiments. Both in the Congo and in the Gambia experiments have shown that the guinea-pig is, perhaps, the laboratory animal most susceptible to *Trypanosoma gambiense*. We therefore determined to employ it, lacking monkeys, in our transmission experiments. At the time of writing both experiments with monkeys remain unsuccessful, and only one, a direct transmission experiment with guinea-pigs, in which the flies were made to feed alternatively on an infected and an uninfected animal, has given a positive result.

Cerebrospinal Fluid in Sleeping Sickness (Trypanosomiasis): 104 Lumbar Punctures.—Cuthbert Christy, in his report on this section of the topic writes: The majority of the punctures recorded in the accompanying tables were performed whilst working with Drs. J. E. Dutton and J. L. Todd in the Congo Free State. All, with the exception of three, were performed by myself, either at Boma, Leopoldville, posts further up the Congo, or since returning to England. Some conclusions drawn from a number of them are published in our last conjoint report. Out of a total of sixty-four natives operated upon, the fifty-four in Table I were proved to be cases of sleeping sickness by the discovery of trypanosomes in the blood or cerebrospinal fluid, or in hydrocele fluid, while in the remaining ten in Table II parasites were never found, although the majority of them were more or less suspicious cases, and all were in hospital at Leopoldville. In thirty-four of the fifty-four sleeping sickness cases the parasites were found sooner or later in the cerebro-

spinal fluid, whereas in twenty of them no parasites could be found, although in one case (17) the fluid was examined on five occasions.

The total number of cases here recorded is too few to permit of any very definite statements, but I think it is sufficient to allow of the following provisional conclusions: (1) That in many cases the trypanosomes never find their way into the cerebrospinal fluid, and in those cases in which they do they are more frequently to be found toward the termination of the disease. (2)That the commencement of the fever or other symptoms is in no way correlated to the entrance of the parasites to the cerebrospinal fluid. (3) That a large number of trypanosomes in the cerebrospinal fluid is rare, but when it does occur there is usually an access of temperature. (4) That the parasites may come and go in the cerebrospinal fluid as in the blood. (5) That enormous numbers may appear in the blood without appearing in the cerebrospinal fluid, and, to some extent, vice versa. (6) That when trypanosomes are present in the cerebrospinal fluid its white cell elements are apt to be increased. (7) That in cases where the parasites gain access to the cerebrospinal fluid early in the disease, mania and other head symptoms are more likely to be prominent.

David Nunes Nabarro, working with Colonel Bruce in Uganda on the Royal Society Commission and of assisting with the joint report on sleeping sickness published by the Royal Society, agreed with many of the propositions enunciated by Colonel Bruce.

Sir Patrick Manson said: If Colonel Bruce's contention is proved, the fact that *Trypanosoma gambiense* is the cause of sleeping sickness is a matter of the highest importance; but if, on the other hand, it be not fully proved, to accept it as such, and to found on the supposition expensive prophylactic measures, would be a serious false move. Colonel Bruce's evidence is principally epidemiological not pathological. In none of his experimental animals did he produce the pathognomonic small-cell infiltration of the perivascular spaces of the brain, nor, so far as I know, have other experimenters been more successful. His epidemiological facts apply only to a very limited region, and it may well be, as with its predecessor *filaria perstans*, that the distribution of the trypanosoma will not correspond with that of sleeping sickness. Indeed, quite recently it has been stated that in the German territory at the south end of the Victoria Nyanza the entire population is infected with trypanosomes, but sleeping sickness is unknown there. If this be true, then the trypanosoma cannot be the only cause, or even a cause, of sleeping sickness. Recent work seems to indicate that the trypanosoma is an element in the causation, but that the determinating cause of the pathogenic condition causing the symptoms of sleeping sickness is bacterial, that is to say, that a combination of Castellani's first and last etiological views is the correct one. Colonel Bruce states that trypanosoma infection is always fatal. I know of one case which three years ago had all the clinical symptoms of trypanosomiasis, and in whose blood Dr. Broden, of Leopoldville, found the trypanosoma, who is now quite well, in fact, in better health than she ever has been for years. Apparently she has overcome the infection.

Dr. Sambon remarked that he could not altogether agree with the statement that the tsetse fly (*Glossina palpalis* was merely a mechanical agent in the transmission of trypanosomiasis, and, therefore, that all stages of development of the parasite takes place in the human body. The tsetse fly no doubt serves as an intermediate host. If the function of this fly is merely mechanical, why do not other biting flies, such as the *Tabanus* and *Stomoxys*, which are also prevalent in the sleeping-sickness areas, also help to transmit infection?

(To be Continued.)

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Twenty-first Annual Meeting, held at Philadelphia, June 2, 3 and 4, 1904.

The President, J. C. Wilson, M.D., of Philadelphia, in the Chair.

Presidential Address.—Dr. Wilson referred to the early history of climatology in this country and sketched the character of Benjamin Rush, saying that he was the first great American physician to enter upon the study of this branch of medicine, and referring to his "Inquiry into the Natural History of Medicine Among the Indians of North America, with a comparative view of their diseases and remedies with those of Civilized Nations." This essay was delivered when Rush was only twenty-nine years of age, and has been regarded as a sort of American classic, embodying at once most important points concerning the red man of that day, and valuable conclusions concerning the value of fresh air, cold water and exercise in health and disease. Dr. Wilson also referred to the part Philadelphia is taking in measures relating to the study, prevention and treatment of pulmonary tuberculosis and to the fact that the transactions of the Climatological Association constitute a valuable record of this moment throughout the country.

Climatology as a Study in the Medical Schools.—This was the title of the paper read by Dr. S. E. Solly, of Colorado Springs. He took pains to ascertain to what extent climatology was included in the regular curriculum. Seven colleges stated that it was included, others stated that there was no regular instruction, but that the different professors, sometimes the professor of medicine and sometimes the professor of therapeutics, referred to the matter of climate in connection with the various diseases discussed. While Dr. Solly recognized the value of Dr. Burney Yeo's dictum that "care without climate is better than climate without care." He urged that we must combat the belief that is now being so much advocated in connection with the open-air treatment of tuberculosis, which is that it is the quantity of the air that is valuable, the quality of the air counting for nothing.

Dr. Carroll E. Edson, of Denver, in discussing Dr. Solly's address, said that medical students and, in fact, most general practitioners do not know how to read weather statistics. The elementary principles—the foundations on which therapeutic application must rest are the fundamental principles of meteorology. The time should be spent upon those preliminaries, or the student directed where he could learn those details in some simple text-book, and time thus spent would go far to help him to read correctly meteorological statistics which are at the foundation of description of relative climates; and it would help especially to keep him from reading or to discount the atrocious falsehoods that are put into hotel, railroad or even into some medical publications concerning health resorts. Dr. Guy Hinsdale, of Hot

Springs, Va., in the discussion said that Dr. Wm. Pepper, who was the Provost of the University of Pennsylvania and one of the Presidents of this Association, was one of the first to realize the importance of teaching climatology in the medical schools. About ten or twelve years ago the speaker was appointed the lecturer on medical climatology in what is known as the Spring Course, or the auxiliary course of medicine in the University of Pennsylvania. For a number of years an elective course of ten lectures was given, beginning with two to three lectures on the general principles of meteorology; and the balance was devoted to the general considerations of climate, with reference, toward the end, to certain health resorts, mineral springs, and so on, in this country. At present there are no lectures delivered in the medical school of the University of Pennsylvania on climatology.

Climate of Santa Barbara, California.—Dr. William H. Flint read a paper on this subject. It was accompanied by tables of temperature, rainfall, relative humidity and wind movement for the past twenty-five years. Dr. Flint said that high fogs occur frequently from May until October, but are comparatively rare during the other months of the year. Being high they do not cause the deposit of so much moisture as one would expect from an eastern fog or "sea turn." At Santa Barbara an invalid can spend about two hundred and fifty entire days annually in the open air without running the risk of a wetting. The invalid will find among the hills warmer winter nights than at any other place in California, and may safely spend his time out of doors in all but ten or twelve days of the year, sleeping comfortably, nearly all the year round, under the stars, whose brilliancy is proverbial.

Climatology of Muskoka, Canada.—Dr. J. H. Elliott, of the Muskoka Sanitarium, read this paper. This region is east of Georgian Bay and north of Toronto, and is called "The Highlands of Ontario." The elevation varies from 600 to 1,400 feet, and the latitude is that of St. Paul and Minneapolis. Lakes Muskoka, St. Joseph and Rosseau have an altitude of 750 feet and are connected by waterways. The region considered covers an area of 1,500 square miles, is well wooded, and has a wonderful variety of scenery, with an adaptability of the surroundings to the needs of the neurasthenic and the tuberculous. There is exemption from hay fever. The severe winters are enjoyed by the robust patient and those whose recuperative powers are good, but patients whose capillary circulation is poor and are anemic cannot stand the cold. The winters are free from rain, fog and dampness. The summers and autumn are ideal. The results in the treatment of tuberculosis are most gratifying. There are two sanatoria managed by the National Sanatorium Association of Canada, on Muskoka Lake near Gravenhurst.

Dr. Lawrason Brown, of Saranac Lake, read a paper entitled "Some Weather Observations in the Adirondacks." (See MEDICAL NEWS, August 20, 1904, p. 341).

Dr. Guy Hinsdale, of Hot Springs, Virginia, read a paper on "The Climate and Waters of Hot Springs, Virginia." (Will appear in a subsequent issue of the MEDICAL NEWS).

A Meteorological Study of the Winter of 1903-4.—Dr. Carroll E. Edson, of Denver, Col., read this paper. His paper was accompanied by a series of charts showing that Denver had a mild winter while the cities in the East and Middle West had an unusually severe one; Boston, New York, Buffalo, Chicago and Denver were compared. Dr. Edson showed that while Buffalo had 112 totally cloudy days out of 152, Denver had only 18. He cited all the factors of climate to show that Denver was far better suited for the outdoor treatment of tuberculous patients than any of the other cities mentioned. He claimed that all fresh air is not equally good and that a location like that of Denver offers, by the conditions of its climate, its lack of storms, its absence of cloud and its warmer sunshine, definite advantages for the tuberculous invalid. In the tables there are side columns giving the mean of the last thirty-three years; so that one can see what the slight variation of this one year has been. In the article on Denver in *Wood's Reference Handbook*, the author anaylzed three successive years in detail.

Ocean Bathing.—Dr. Philip Marvel, of Atlantic City, N. J., read a paper on this subject. He cautioned against too prolonged an exposure in the ocean, the habit of going about the beach in wet clothing and too frequent indulgence. The body temperature is lowered and the pulse beats reduced and the economic forces temporarily inhibited, and in some instances seriously deranged. Sea-bathing is contra-indicated in those cases in which the arterial elasticity for any reason has been changed or lost as in arteriosclerosis and capillary fibroses; when the peripheral vessels cease to respond to reflex stimuli; in all cases of recent rheumatism or gastro-intestinal disease.

The Delirium Noticed in Heart Disease.—Dr. Roland G. Curtin, of Philadelphia, read this paper. He said that the great difficulty in studying and classifying the symptoms of advanced heart disease is that it is often hard to sharply separate the symptoms depending on the primary condition from those of the commonly associated complications. The cases are rare, Dr. Curtin having met with only four, in which the insanity was continual. The delirium of the last stage of heart disease differs from that in other diseases in being more melancholy and with suicidal tendencies in some cases. The delirium is almost always after sleeping and it is easy to arouse the patient from the delirious state. The symptoms are quite acute and active in cases unassociated with dropsy and great weakness, but less so in cases with anasarca; more frequent in those advanced in life and the symptom is grave, from which the patient rarely rallies.

Dr. Robert H. Babcock, of Chicago, opened the discussion, saying that after a thorough search he had found only three articles published on the delirium of chart disease. Riegel's paper, published in 1879, described this form of delirium as a toxemia due to the administration of drugs in the attempt to remove the dropsies and other symptoms incident to the cardiac inadequacy. The patients later may pass into a state of collapse from which they may not recover. The second paper bearing on this subject was entitled "Toxemic Delirium of Heart Disease," published by Eichhorst in the *Zeitschrift für klinische Medizin*, in 1898. Eichhorst calls attention to mental disturbance in certain cases of mild cardial disease which enter the hospital in a state of broken compensation and of dropsy. During the attempt to relieve the dropsy by means of digitalis and diuretin, delirium developed, which either active or of a low, muttering kind, and was preceded by somnolence. As the dropsy disappeared the patients became rational and returned to their former normal state. Eichhorst believed these symptoms were due to the

absorption of toxins incident to the removal of the edema and that they were not due to drugs, since these drugs were not administered in sufficient doses to produce these effects and did not produce like effects in other patients. Dr. Babcock had seen two cases during the past winter in whom this symptom developed. One was a case of mitral insufficiency, with chronic fibrous mediastinal pericarditis, with dropsy, and during the administration of large doses of diuretin for the purpose of carrying off the dropsy, this patient became delirious, his delirium manifesting itself at night. The second was an elderly man, with chronic myocarditis, the vascular form of aortic regurgitation, and chronic interstitial nephritis. This man, when dropsical and the edema was being removed by proper remedies, became mildly delirious, not recognizing objects in the room; talking about business and mistaking a picture in the room for a powerful Irishman who wanted to get into the bed and turn him out. He frequently said that he could breathe if he could start his breathing first before that big Irishman in the corner did. It was a singular form of delusion. In both these instances Dr. Babcock inclined to attribute the mental disturbance to the effect of toxins; although it is conceivable that some degree of cerebral edema might be responsible for the condition. He thinks it is one of great importance and which one should study with a view to more definite facts concerning this symptom, since it appears to be a very important one. One case recovered.

Dr. Beverley Robinson, of New York, said that one seldom has disease of the heart without other disease existing elsewhere as in the kidneys or the brain. Faulty metabolism, not connected with the heart particularly, and reabsorption of poisons through a defective action of the kidneys account for this. Dr. Robinson said that he had seen in private practice particularly, what he considered to be a neurotic heart. They are associated with anemia, a diastolic bruit, low hemoglobin, and a low specific gravity of urine.

Dr. De Lancey Rochester, of Buffalo, said that in reference to diuretin, he recalled two cases seen this winter in which there was apparently no disease of the kidney but where there was pronounced cardiac disease; cardiac dilatation resulting from overstrain on top of a previously existing mitral lesion and edema and ascites. He used diuretin to relieve the edema, and in turn a pronounced delirium followed the use of diuretin. Diuretin, or any other stimulating diuretic, is, in his opinion, contra-indicated in any case of cardiac disease associated with which there is existing disease of the kidney; for the relief of the edema we should rely upon the sweating apparatus rather than upon stimulating the kidney; but in these two cases there was apparently no disease of the kidney; the urea was apparently perfectly normal; but still, following the use of diuretin, delirium resulted in quite a pronounced degree. Whether this particular drug has a poisonous effect he does not know; but it was interesting to him when Dr. Robinson mentioned that delirium had occurred during the use of diuretin. In answer to the question from Dr. Babcock as to what dose of diuretin Dr. Rochester used, the latter replied, "one gram four times a day."

Dr. James M. Anders, of Philadelphia, said that after the tricuspid valve becomes incompetent the heart and the lungs no longer bear the entire brunt of the cardiac lesions, but now every organ of the body shares in the work of carrying the burden. We have venous congestion—increased pressure in the venous side of the circulation; and the point that the profession ought to remember in this connection is, that this is a distinctly pathological condition; it means starvation of tissue throughout the entire body; it means accumulation of waste products in every organ in the body; it also implies distinct tissue alterations or changes in the various organs of the body, including naturally the brain. Now other considerations enable the profession to understand why it should have disturbance of the function of the brain in these cases, the same as disturbance of the function of the liver, the gastro-intestinal tract, the kidneys and other organs of the body. This is the explanation of most cases of delirium that sometimes arise in the course of organic valvular disease. Now there is one other causative factor often lost sight of, and that is, the altered blood changes. Under these circumstances a general arteriosclerosis and fibrosis of the viscera are engendered and delirium may develop before any evidence of failure of compensation exists.

Dr. R. G. Curtin, of Philadelphia, said in answer to Dr. Robinson's statement in regard to the associated kidney disease, that was excluded as far as possible to exclude it; there was no albuminuria in the cases at the time the observations were made. He has seen a great many cases where there has been a slight amount of albumin in the urine, in which there has been delirium; but he did not report cases in which this seemed to be a factor. Also, in regard to the subject of diuretin—only four of the cases were treated by diuretin, and one of the cases perfectly recovering was one of the cases put upon that drug. He has used this drug extensively during the last ten years and has never suspected it as a cause of delirium or of any other nervous manifestation.

Mechanical Treatment of Heart Disease.—Dr. Charles E. Quimby, of New York, read a paper with this title. He advocated the use of the pneumatic cabinet for cases of aortic regurgitation. It affords relief to a crippled and overtaxed heart and excels any other measure in the results obtained. In mitral regurgitation the effect is often as immediate and definite, but less in degree and duration. In angina it is *facile princeps* in the rapidity and permanency of relief afforded.

The General Principles of Management of Pulmonary Tuberculosis.—This was the subject of Dr. S. G. Bonney, of Denver, Col. He advocated sanatorium treatment only in certain cases. Continued vigilant supervision is necessary for some cases, but unfortunate or detrimental to others. The influence of the physician himself is the predominant factor. The sanatorium itself being in most instances a most beneficial accessory to the good result rather than a *sine qua non*.

Is Milk a Factor in the Spread of Tuberculosis.—Dr. J. O. Cobb, of the United States Public Health and Marine Hospital Service, read this paper. He holds that milk is not a factor of any importance. He showed that in many countries where tuberculosis prevails milk is not used to any extent as food. The cattle of the islands of Guernsey and Jersey are free of tuberculosis but the people have it as usual. The Chinese and the Alaska indians have tuberculosis but do not use milk as an article of diet. They sometimes use it if prescribed by physicians or through living with Europeans.

Dr. A. Jacobi differed from the views expressed and said that negative assertions do not prove any-

thing against a single positive one. The literature is too rich to be overlooked. He believes in sterilization in all cases of doubt; in mixing milk from thirty or forty cows so that by dilution there may be safety in case one is infected.

Some Cases of Pus Infection Simulating Pulmonary Tuberculosis.—Dr. Robert H. Babcock, of Chicago, read this paper. The histories of five cases were given. They are believed to represent a class of cases which present considerable difficulty in differential diagnosis.

Dr. J. O. Cobb, of Detroit, Mich., in discussing Dr. Babcock's paper, said he thought that Dr. Babcock's cases are really infected pneumonias, because the profession knows that the pulmonary tissue acts as a screen and sieve to take out of the circulation any infective material in it. It is also aware that interference with a gluteal or rectal abscess of tuberculous origin often sets up a very rapid infection of the lungs. The lungs and liver are essentially the sieves for the circulation, and he thinks that is the explanation of Dr. Babcock's cases of lung consolidation in the case of an ordinary pus infection elsewhere. Now, if that pus infection elsewhere were due to streptococci and they got into the circulation and then were screened out in the lungs, then one would have a pyemia—a very rapid pyemia which would destroy the patient. But it has been brought forward that even gonococci will be washed out in the lungs and produce a consolidation and still not break down; but streptococci will invariably break down, but not always diplococcus infection. This has been illustrated from mastoid infection where it is not due to the streptococcus, for often one will have an infective pneumonia, and he thinks that is the explanation of Dr. Babcock's cases.

Dr. Babcock said that inasmuch as circulatory derangements within the abdomen may be secondary to pulmonary disease, might it not be that circulatory derangements within the lungs may be secondary to abdominal disease? He is interested in Dr. Cobb's suggestion that the abnormal pulmonary findings were due to infection. So it is; but it did not seem to Dr. Babcock that in any one of his cases there was actual lung consolidation. The dulness was not intense enough, nor were the breath sounds distinctly bronchial. It impressed him much more that there was simply some circulatory disturbance in the two first cases; that is, those cases in which there was pus infection from suppurative peritonitis. Therefore he was inclined to attribute the changes to pulmonary anemia; for if pulmonary anemia does produce relaxation and diminution in the volume of the lungs with passive decrease in the capacity of the thorax, it seemed to him that such a condition could be responsible for the slight impairment of resonance and the change of respiratory murmur noted and which was so slight as to be scarcely definable. The general condition is favorable for the production of pulmonary anemia in such cases. In the case of gall-bladder and empyema, there was unmistakable dulness in the posterior aspect of the right lung. What that was due to he could not say, he simply knows it cleared up, and it is interesting to speculate whether it was due to mechanical pressure from a distended gall-bladder or was some circulatory derangement, as a pulmonary hyperemia, depending upon the sensory irritation; or whether it was a manifestation of a lung reflex. Striker narrates a very interesting case in which he saw a woman with very distressing and alarming symptoms of pulmonary hyperemia and distention of the right heart secondary to a cholelithiasis. Relief from the pain of the cholelithiasis brought with it next morning a disappearance of the alarming symptoms. This suggested to Dr. Babcock that perhaps in this case the pulmonary findings were really due to sensory irritation—ill defined to be sure, but sensory irritation nevertheless, from the distended gall-bladder. He would like for a moment to dwell also on the importance of a leucocyte count. This has become so common that one always thinks of it and resorts to it, in any case of suspected pus infection; but in these cases, which come to the profession sometimes with symptoms very suggestive of incipient tuberculosis and in which the pulmonary findings are so vague, that one is not quite satisfied whether pulmonary disease does or does not exist—he believes the leucocyte count is of value. Leucocytosis does not exist in pulmonary tuberculosis unless there be mixed infection; and when mixed infection takes place, the pulmonary changes are so pronounced that anyone can discover them; whereas in very early tuberculosis —those cases in which there is a desire for the good of the patient to discover the disease at a time when it may be amenable to treatment—the leucocytes are not increased, but are actually diminished.

CONGRESS OF INTERNAL MEDICINE.

Twenty-first Session, held in Leipzig, April 18, 19, 20 and 21, 1904.

(Continued from Page 576.)

Physiology of Cardiac Nerves.—By means of a new method, Ascher comes to the following conclusions. The activity of the cardiac nerves depends upon the amount of nutrition. Every sudden change of temperature will diminish the irritability of the vagus; gradual lowering of the temperature will also reduce it, while raising the temperature is without effect. There is also an increased irritability if the intracardial pressure is raised, but this is soon followed by adaptation. The difference between inhibitory and accelerating nerves does not lie in the nerves themselves, but in the endbodies. These are affected also by iodothyrin, which paralyze the action of the atropine.

Inhalation of Drugs.—An active diffusion through the epithelium of the bronchi and the delicate wall of the pulmonary vessels probably occurs, for Reitz could detect many inhaled drugs in a short time in the urine and blood. Thus, much more iron could be detected in the blood when organic iron was sprayed into the throat than when it was given by mouth. Schmidt thinks that considerable absorption already occurs in the trachea.

New Diagnostic Sign of Pancreas Disease.—Since the pancreatic juice contains the only ferment which is able to digest the nuclei of tissues, A. Schmidt gives suspicious cases small pieces of meat in wafers, and then examines the feces. In severe lesions of the pancreas, the muscle remnants will appear with intact nuclei, while in other diseases or in health the nuclei will be digested.

Hemolysis.—Koeppe regards the laking of blood under various conditions as a purely physical or chemical process. The red cells are all surrounded by a membrane containing a fatty and an albuminous principle. By repeated freezing and thawing, by the addition of water and after the use of electricity, the membrane is simply torn; heat will melt the fatty constituent; acid will split it into alcohol, and fatty acid alkali will saponify it, while serum-hemolysis is brought about by disintegration of the proteid principle.

Streptococcus Serum.—Menzer employs a serum which has not been passed through animals and has seen

good results in chronic, protracted cases of muscular rheumatism and in the mixed infection of tuberculosis.

Action of Digitalis.—Brandenburg finds that besides its other properties, digitalis renders the heart muscle less susceptible toward external influences. If digitalin is injected into the heart of a frog, electric currents will no longer bring about extrasystolic contractions.

Virulence of Pneumonic Sputum.—If white mice are inoculated with one cubic centimeter of the same pneumonic sputum, they generally die within the same time, so that these animals may be used to measure the virulence of a sputum. Stuertz has made the interesting observation that the prognosis can be determined in this manner for the virulency is very high in severe or fatal cases. Exacerbations can be determined more readily this way than by physical signs and earlier than by other symptoms.

Levulosuria in Liver Disease.—In more than 80 per cent. of all hepatic cases and in less than 20 per cent. of those without liver lesion, Strauss could bring about an alimentary levulosuria. This may be a valuable aid in the diagnosis of difficult cases.

New Eye-Symptom in Diabetic Coma.—In three cases of diabetic coma, P. Krause observed a well-marked hypotonia of both bulbs 15 to 32 hours before death. In other comatose conditions this symptom was not present. The cause could not be ascertained, and it seems certain that diminution of blood-pressure and of the amount of water, or the pressure of acetone, diacetic or oxybutyric acids have nothing to do with it. The anatomical examination of the bulbs was negative.

Motor Function of the Vagus.—Three causes are generally given for diffuse esophageal dilatation: Cardiospasm, paralysis of the musculature and atrophy of the vagus. Starck tried to bring about dilatation in the dog by resecting the vagus in the neck, above and below the helus of the lung and above the cardia. The results are: Reaction in the neck and above the hilus will paralyze the musculature and thus favor dilatation. Atrophy of the vagus is only a cause if the musculature is not hypertrophied. Since this is, however, the case in most instances, vagus degeneration will rarely play an etiological rôle. No dilatation occurs if the vagus is resected beneath the hilus, since the motor fibers reach the esophagus above the hilus. The absence of relaxation of the cardia during swallowing does not form sufficient impediment to cause dilatation.

Chemistry of the Diazo Reaction.—Clemens has succeeded in obtaining the substance underlying the Ehrich diazo reaction, in concentrated form, but could not separate it from all impurities.

Fat in the Urine of Nephritis.—It was formerly supposed that the pressure of fat in the urine of patients suffering from chronic parenchymatous nephritis is caused by fatty degeneration of the cells, but Winternitz believes it is due to the fact that the renal filter permits the fat of the blood to pass through. The amount of fat may reach a very high degree.

Treatment of Hyperacidity.—Since the amount of chlorine in the feces in hyperacidity of the stomach is often abnormally low, it is safe to assume that the absorption of chlorides is very active. Leo, therefore, restricted all salt from the food, but without effect. Better results were obtained with rectal and gastric lavage with four to ten per cent. solutions of salt; the pain and hyperchlorhydria often disappeared in a short time.

Influence of Fever upon Various Diseases.—Dehio investigated the influences of fever induced by injecting peptone upon lupus, recent syphilis and acute gonorrhea. Among thirteen cases of lupus, three were cured completely. In six cases there were recurrences which were treated with the sharp spoon. In a few cases of gonorrhea, the discharge ceased completely.

Effect of Different Proteids on Diabetes.—Falta studied the influence of casein, serumalbumin-fibrin, globulin, hemoglobin and egg-albumin in four cases of severe diabetes. It seems that the sugar is most abundant with those proteids which are most rapidly decomposed (the first-mentioned members of the group). Coagulated egg-albumin seems to be more harmful than incoagulated.

Disturbances of Speech in Neurasthenia.—Four forms of disturbance of speech in neurasthenia are recognized by Gutzmann: (1) Disturbances in the memory of speech; (2) disturbances of association; (3) easy fatigue of the muscles; (4) emotional effects, and (5) disturbances of co-ordination, especially stuttering.

Estimation of Cellulose in Feces.—Simon dissolves the cellulose by boiling the feces with 50 per cent. potash-lye, and then precipitates with 96 per cent. alcohol. In constipation the cellulose seems to be used up better than under normal conditions.

NEW YORK ACADEMY OF MEDICINE.

Section on Genito-Urinary Diseases.

Stated Meeting, held May 18, 1904.

The President, James Pedersen, M.D., in the Chair.

Perineal Prostatectomy With Severe Cystitis, Followed One Year Later by Phosphatic Calculus; Litholapaxy; Cure.—Dr. A. A. Berg reported the case of a man, sixty years old, who came to the Mount Sinai Hospital one year ago last summer with the usual symptoms of prostatic hyperthrophy. There were from two to three ounces of residual urine. The prostate was small and atrophic rather than hypertrophic. There was considerable cystitis and the patient suffered a great deal under general anesthesia. Perineal section was made for the removal of the prostate. This gland was found to be very small, with the middle lobe about the size of a hazelnut; the operation was easily performed, lasting only twenty minutes. The drainage was retained in the bladder six days. Then the improvement in the cystitis was so evident that the drainage was removed. He continued to wash out the bladder daily with weak solution of nitrate of silver. The wound closed completely in three weeks but the patient was kept in the hospital until the cystitis showed evidences of improvement. He was then discharged with instructions to return for further bladder washings. This he failed to do. The symptoms of retention were completely relieved and there was no residual urine; he passed water with normal frequency and thought he had recovered normal conditions. The patient then was lost track of until last summer when he appeared complaining again of symptoms of cystitis. The cystoscopic examination showed a calculus a little larger than a hazelnut lying at the base of the bladder and a considerable cystitis. By irrigations of 1-5,000 silver nitrate solution the existing cystitis was reduced before operation was proceeded with. After two weeks in the hospital the cystitis improved and then, under cocaine anesthesia, with a lithotrite the stone was crushed and the particles removed with the evacuator. The cystoscopic examination showed that all the particles of stone had been removed. The patient was kept in the hospital for two weeks and his bladder repeatedly washed. Later he returned and reported that all was doing well, his urine was clear and he had no difficulty in voiding it. He got up but once at night to pass his urine and

during the day he urinates about three times. He says that he is completely cured. The case was reported as one of atrophic prostate with evidences of cystitis and subsequent formation of a calculus.

Case of Prostatism.—Dr. Edward L. Keyes, Jr., reported such a case in a patient upon whom he operated two years ago. The symptoms of prostatism only existed six weeks prior to operation. This patient had retention and a violent cystitis following. Because of the serious implication of the kidney he felt justified in advising operation. The prostate was burned down and he never saw an individual bear a perineal tube worse. The wound healed kindly and the patient was able to empty his bladder except about one-half an ounce. He was very sensitive and permitted no instrumentation until about six months later when the searcher revealed a stone. The removal of this calculus relieved all symptoms.

Complete Destruction of the Kidney by Multiple Metastatic Abscesses.—Dr. A. A. Berg said that he had presented a similar case to the Section some two months ago. The patient was a young girl, an operator, who came into the surgical service of Dr. Gerster during the month of Februry, 1904. The history given was that some one month before she had a paronychia on one of her fingers (this was obtained from her subsequent to the operation). For one month she had considerable pain in the right hypochondrium, with fever, chills, loss of strength and much prostration. Urination was comparatively normal, thrice daily and not at all during nights. She said that her urine was clear and never contained blood. The physical examination showed all the internal organs to be normal, but in the right hypochondrium there was a large mass, the size of two fists, very tender and hard, with the colon in front and to the inner side of it; it was immovable with respiration. Examination of the bladder with the cystoscope showed everything to be normal. The urethral orifice was normal. Bilateral catheterization was undertaken and, on the right side, the catheter left in one-half an hour drained no urine; but on the left side one-half an ounce was withdrawn. Cryoscopy of the urine from the left side showed its freezing point to be 1.7; that of the blood was .58. A tumor of the kidney, probably of suppurative type, was diagnosed and operation was advised and consented to. Upon cutting down upon the kidney it was found to be filled with multiple abscesses; no kidney tissue could be recognized as such. There were hundreds of small abscesses from the size of a pin-head to a hazelnut. There was absolutely no trace of kidney tissue visable. This, of course, accounted for there being no kidney secretion on the right side. The only cause for this condition that could be found was the paronychia and to this was attributed the suppurative process. Last summer, he said, he had operated upon a similar case but the site of infection was from an abrasion on the side of the foot from the wearing of a tight shoe. In the case presented the miliary abscesses were curetted and the cavities packed with gauze and allowed to fill up from the bottom. The patient rapidly gained in weight and in strength and has been in a healthy condition ever since.

Dr. F. Tilden Brown said that in those cases of suppurative processes in the kidney were more commonly perinephritic suppurations secondary to a streptococcus infection from some cutaneous surface. He asked if any subsequent examination had been made to ascertain whether or not the urine was now coming from the right ureter? Whether the kidney tissue that was left had been able to functionate or show any activity whatever? He said he was inclined to suspect some antecedent suppurative process in the kidney. He said it would be interesting to learn if there ever had been cases similar to this in which there was no history of urine or pus passing.

Dr. Robert T. Morris said that two years ago he split a kidney in its entire length and found a large number of abscesses in the parenchyma and he decided to risk leaving the kidney; therefore, it was drained and the patient made a good recovery, and he subsequently found the kidney was doing very good work. There must have been several hundreds of these small abscesses left that were not opened. The patient made a very good recovery.

Dr. Howard Lilienthal said he had seen several of these cases and one he had reported several years ago in the *Annals of Surgery*, in which there were miliary abscesses in each kidney following an attack of erysipelas of the face. Repeated double nephrotomy was performed and the patient finally recovered. In the cases that he had seen the urine contained no pus at all. As a result of experimental work and post-mortem findings he said he had come to the conclusion that these metastatic abscesses were practically always found in the cortex of the kidney, and at first did not cause any changes of any note in the urine, not even albumin or casts. In such a case as reported by Dr. Berg it seemed to him likely that there must have been a plug or some sort of pressure on the ureter to account for the total absence of urine from the ureteral catheter. It was a well-known fact that in destructive processes of the kidney, when even a little bit of the kidney substance is left this remnant will secrete urine. He thought a total anuria from that side must have been of neurotic origin or from pressure of some kind upon the ureter. In regard to perinephric abscesses occurring under these circumstances he did not believe that they ever occurred as a primary infection, but always were the result of a breaking into the perinephric tissues of cortical abscesses in the kidney. He could not answer why abscesses should form in the perinephric fat as the result of metastatic invasion, but he could see every reason for believing that these abscesses might occur in the cortex. When these abscesses break down into the perinephric fat then we would have perinephric abscesses. Perinephric abscess *per se* does not occur except as secondary to suppuration in the kidney or some neighboring organ.

Dr. A. A. Berg, in answer to the question raised by Dr. Brown, answered that a subsequent cystoscopic examination had not been made. He believed the suggestion was a good one and he would carry it out, although he did not believe that much would be found. Regarding an old obstruction of the ureter as explaining the right-sided anuria, there were no symptoms of it given in the history. Some albumin and casts were found in the urine but no pus or blood and no increased urination. Examination of the mouth of the ureter in those cases where secretion of urine had been brought to an end by plugs in the ureter usually shows some slight changes, either a retraction or ulceration, *e.g.*, in a pyogenic pyonephrosis. In the case reported the ureteral orifice was absolutely normal. The catheter was introduced about 8 or 10 inches and met with no obstruction and he did not believe there was any plug in the ureter. With regard to the condition of the kidney when it was cut down upon Dr. Gerster remarked at the time that he had never seen such complete destruction of the organ. An extensive search of the remnant of the kidney was made but nothing was found, only a large number of abscesses surrounded by inflammatory tissue.

With regard to the question of a nephrotomy or a nephrectomy for metastatic miliary pyogenic emboli in the kidney, this was a wide question and it should be

remembered that pyogenic organisms act upon the kidney in many ways; they can produce a chronic contracted or a chronic diffuse nephritis like Bright's disease; such cases often do very well with incision and drainage. On the other hand pyogenic organisms might produce large infarctions of the kidney which undergo suppuration and, in such instances, he believed nephrectomy the better procedure. In the type of cases, such as presented in which there was a most complete destruction of kidney substances, a nephrotomy would be of no value. He agreed that, as a rule, perinephritic abscesses in any of these cases was the result of kidney suppuration. The kidney suppuration occurs first and then there was a perinephritic suppuration following.

Dr. F. Tilden Brown said that Dr. Lilienthal's remark about the nephritic abscesses preceding the perinephritic abscesses seemed to him to be in accord with the facts as shown in the majority of the cases, but he did not believe that the profession could accept that statement as being invariably the case. He said that it seemed to him that in view of the fact that a number of the cases were not examined after considerable perinephritic abscesses had been evacuated the condition of the kidney itself was not determined and, therefore, it could not be said that they were always normally functionating. One should not say that without exception perinephritic abscesses were secondary to abscesses in the cortical portion of the kidney. Dr. Brown reported cases of two brothers one year ago; both had perinephritic abscesses secondary to kidney lesions; examination of the kidney failed to reveal anything although the kidneys were not brought to view.

Dr. L. Bolton Bangs said he would corroborate what Dr. Brown had just stated. He had opened and drained perinephritic abscesses which had no connection, at least at the time of operation, with the kidney substance, and none subsequently because the patients had recovered and there had been no occasion to attack the kidneys except for purpose of examination.

Dr. Lilienthal said that he explained these cases by assuming that these abscesses had perforated into the perinephritic tissues. Many of these perinephric abscesses he had opened and drained and had not found it necessary to go further. But there were others that he had open and drained and had subsequently been compelled to go further, when he had found other abscesses in the kidney substance that had not been opened and had not drained.

Funiculitis.—Dr. James Pedersen presented the young man with funiculitis, whom he had shown at the March meeting of the Section. He presented him to show that under purely expectant treatment the tumefaction had considerably subsided. A specific urethritis is still present. As all attempts to relieve this, even by means of hand injection, have caused a threatened relapse of the epididymitis, all local treatment has been abandoned in favor of constitutional treatment with cod-liver oil, Russell's emulsion and iron.

A Case of Atrophy of Testis, Hardened Epididymis, Hydrocele and Varicocele.—Dr. Ramon Guiteras presented a patient, twenty-eight years old, who had had several attacks of urethritis and, on one occasion, a double epididymitis. Now his right testicle was atrophied, and there was a hardened epididymis and vas deferens on the left side with some fluid in the tunica vaginalis on both sides. The hardness of the epididymis was very peculiar when last examined. He simply presented the case as one of interest. There was also a varicocele on the left side.

Calcareous Accumulation in the Bladder and Urethra Giving Rise to Retention.—Dr. Ramon Guiteras said that two years ago a patient entered the Columbus Hospital with a diagnosis of stone in the urethra. Examining the patient under ether he was with difficulty able to pass a tunnel sound into the urethra and he found that a stone occupied the whole caliber of the urethra; he finally managed to pass the stone and enter the bladder. He then made a perineal section and, instead of finding one stone, he found the prostatic and membranous portion and part of the bulbous, filled with small calculi and pieces of calculi resembling those that had been crushed. The bladder, too, seemed to be packed with calculi in pieces, and one was about the size of a pigeon's egg. With forceps he managed to extract all the pieces of calculi without crushing them. One would have believed that a very large calculus had been previously crushed, but there was no such history given. The bladder was much thickened. With two fingers in the rectum and the other hand placed suprapubically he could feel what appeared like the crop of a fowl filled full of gravel.

(To be Continued.)

BOOKS RECEIVED.

Chir. Orthopedique. By Profs. Paul Berger and S. Banzet. 624 pages. Illustrated. G. Steinheil, Paris.

The Summer Diarrhœas of Infants. By Dr. H. Illoway. 12mo, 150 pages. E. R. Pelton, New York.

Modern Ophthalmology. By Dr. Jas. Moores Ball. 8vo, 820 pages. Illustrated. F. A. Davis Co., Philadelphia.

Anti-typhoid Inoculation. By Dr. A. E. Wright. 21mo, 76 pages. Illustrated. Archibald Constable & Co., Ltd., Westminster.

The Purin Bodies of Foodstuffs. By Dr. I. Walker Hall. Second Edition, 12mo, 201 pages. P. Blakiston's Son & Co., Philadelphia.

Veterinary Pathology. By Drs. Friedberger and Frohner. Translated by Dr. M. H. Hayes. Volume 1. 8vo, 519 pages. W. T. Keener & Co., Chicago.

Diseases of the Nose and Throat. By Dr. D. Braden Kyle. 8vo, 669 pages. Illustrated. W. B. Saunders & Co., Philadelphia, New York and London.

A Reference Handbook of Medical Sciences. Edited by Dr. Albert H. Buck. Volume VIII. 8vo, 784 pages. Illustrated. Wm. Wood & Co., New York.

Bacterical and Clinical Studies of Diarrheal Diseases of Infancy. By Drs. Simon Flexner and L. Emmett Holt. 8vo, 202 pages. The Rockefeller Institute for Medical Research.

Radio-therapy, Photo-therapy, Radium and High-frequency Currents. By Dr. Chas. Warrenne Allen. 8vo, 618 pages. Illustrated. Lea Brothers & Company, Philadelphia and New York.

Roentgen Rays in Therapeutics and Diagnosis. Drs. Allen Pusey and Eugene Wilson Caldwell. Second edition. 8vo, 334 pages. Illustrated. Lea Brothers & & Co., Philadelphia, New York and London.

Practical Treatise on Genito-Urinary, Venereal Diseases and Syphilis. By Dr. Robert W. Taylor. Third edition. 8vo, 757 pages. Illustrated. Lea Brothers & Company, Philadelphia and New York.

Health and Disease in Relation to Marriage and the Marriage State. By Drs. H. Senator and S. Kaminer. Translated by Dr. J. Dulberg. Volume 1. 8vo, 498 pages. Redmond Co., New York and London.

System of Practical Surgery. By Drs. von Bergmann, von Bruns, and von Mikulicz. Translated and edited by Drs. Wm. T. Bull, E. M. Foote, C. P. Flint and Walton Martin. Volume 4. 8vo, 757 pages. Illustrated. Lea Brothers & Company, Philadelphia and New York.
